In general, the most promising advance in soil N testing in the humid regions of the United States has been the presidedress soil nitrate test (PSNT) originally developed for corn and later used for a wider range of agronomic and vegetable crops (Magdoff et al., 1984; Bock and Kelley, 1992). The PSNT was conceived and evaluated to address the problem of overfertilization of corn with N in the Northeastern United States, particularly in fields with histories of manure and legume use where residual organic N would likely provide an appreciable percentage of the total N requirement for many nonleguminous crops. The PSNT has four basic tenets: (1) all fertilizer N for corn except for a small amount banded at planting, should be applied by sidedressing when the crop is beginning its period of maximum N uptake, usually early June; (2) soil and climatic conditions prior to sampling integrate the factors influencing the availability of N from the soil, crop residues, and from previous applications of organic wastes; (3) a rapid sample turn-around (<14d) by a testing laboratory is possible, thus allowing time for farmers to collect the soil sample, submit it to the laboratory, have it an analyzed, receive the results and recommendations, and then apply (or not apply) sidedress N before the corn crop becomes too large for equipment to move through the field; and (4) farmers will normally only sample to a depth of 30 cm, the recommended depth for the PSNT sample. In practice a PSNT sample is collected early during corn growth, when the corn plants are ~30 cm in height. The sample is air-dried rapidly, or ovendried at <60°C, after spreading the soil in a thin (<1 cm) layer. Extraction and analysis for NO₃-N proceed as described above for residual inorganic N. However, while the PSNT actually measures inorganic soil N, it is not a measure of residual inorganic N, but an indirect, field-based expression of a soil's capacity to provide an adequate supply of inorganic N during the growing season (i.e., of the soil N mineralization potential). The PSNT has been evaluated in over 300 field studies in the Northeastern and Midwestern United States and has been repeatedly shown to be successful in identifying N sufficient soils (Magdoff et al., 1990; Bock and Kelley, 1992; Meisinger et al., 1992; Sims et al., 1995; Jaynes et al., 2004; Muñoz et al., 2008). Some of the logistical difficulties associated with the need for rapid sample analysis have

been overcome by the development of "quicktest" kits and specific ion electrodes that can be used in the field (Jemison and Fox, 1988).

Recently, the Illinois soil N test (ISNT) has been proposed as a means to identify fields where corn would not be responsive to N fertilization. Initially, Mulvaney et al. (2001) found that soils that did not respond to fertilizer N mineralized larger quantities of N and this mineralization was correlated to a decrease in soil amino sugar N. However, the fractionation of soil N developed by Mulvaney and Khan (2001) to determine amino sugar N is too cumbersome for routine soil analysis. Therefore, Khan et al. (2001) developed a simpler method for estimating amino sugar N, which has come to be known as the ISNT. The ISNT estimates amino sugar N and has been found by some to reasonably identify soils where no response to fertilizer N would be expected in corn. The procedure as described by Khan et al. (2001) requires incubation of 1 g of air-dried soil with 10 mL of 2 M NaOH in a 472 mL wide mouth jar. The sample is heated for 5 h at 48°C-50°C on a hot plate. Ammonium and amino sugar N is then liberated as NH3 and collected in an H3BO3 indicator solution. After its original publication, the method underwent modest modifications including a recommendation to rotate the sample jars on the hot plate (Mulvaney et al., 2004) or to enclose the hot plate and incubation vessels in a box (Klapwyk and Ketterings, 2005) in order to reduce spatial variability within the hotplate.

Since its release, the effectiveness of the ISNT has received mixed reviews within the soil science literature. Klapwyk and Ketterings (2006) reported that when used in combination with soil organic matter the ISNT appeared to do a good job of identifying corn fields that may be responsive to additional N fertilizer. However, Barker et al. (2006) reported that the ISNT was not able to distinguish between responsive and nonresponsive Iowa soils. A strong correlation was found between the ISNT and total soil N, hydrolysable NH4-N, and hydrolysable NH4 + amino sugar-N. They concluded that the ISNT extracted a consistent fraction of soil total N and as a result was not able to predict potentially labile soil N fractions. As a result, the authors recommended against the use of the ISNT to guide N fertilization in Iowa corn production. Similarly, in an on-farm N fertilizer response trial conducted by Spargo et al. (2007), the ISNT was found to extract a consistent percentage of total soil N and was deemed a poor predictor of labile soil N. Osterhaus et al. (2008) conducted 80 corn N response experiments in Wisconsin and reported that ISNT values were not related to the observed economically optimum N rate and that the ISNT had no ability to separate N-responsive from unresponsive sites. They suggested that the ISNT measures a constant fraction of soil organic N instead of measuring the readily available N pool, as would be required for an accurate soil N test designed to predict soil N supplying capability and corn N response. In contrast to these studies, Lawrence et al. (2009) found that adjusting ISNT values based on soil organic matter content (as estimated by loss-onignition [LOI]) resulted in accurately identifying 83% of the N responsive sites in a 34-site field study using corn planted after grass-legume sod. They emphasized the importance of the timing of soil sample collection (within 5 weeks of sod plowdown)

and the need to include N credits for sod decomposition to the successful use of the ISNT. These mixed results indicate that the ISNT should be used with caution, and perhaps in conjunction with other soil measurements (e.g., organic matter); it is, however currently offered as a routine soil N test by some commercial and state soil testing laboratories.

13.2.4.4.2 Considerations in Interpretation of Nitrogen Soil Tests

Most recommendations for the amount of N required for optimum plant growth are not based on soil N testing, but on field calibration studies quantifying plant performance in response to N inputs (fertilizers, manures, biosolids, etc.). Widespread, commercial-scale use of soil N testing today is confined to certain areas and crops, such as the PSNT and ISNT for corn in humid regions or residual inorganic N testing for grain crops in arid regions. Recommended N rates for the major grain crops, such as corn, wheat (Triticum aestivum, L.), and sorghum (Sorghum bicolor [L.] Moench) are initially determined from equations using the expected, realistic yield goal and a conversion factor appropriate to that crop. For example, for corn, the fertilizer N rate recommended in many U.S. states is arrived at by directly multiplying the realistic yield goal by an empirically determined factor that ranges from 17 to 18kg fertilizer N per Mg of expected yield (equivalent to 1.0-1.2lb fertilizer N per bushel of expected yield). Modifications (reductions) to this recommendation are then made based on PSNT values, residual soil inorganic N, the previous or intended use of other N sources (animal manures), documented N inputs from other sources (high NO₃-N irrigation waters), and credits for N supplied by a previous legume crop in the rotation (e.g., alfalfa, soybeans). Tisdale et al. (1993) summarized the general approach used to make N recommendations:

$$N_{\text{fertilizer}} = N_{\text{crop}} - N_{\text{soil}} - (N_{\text{organic matter}} + N_{\text{previous crop}} + N_{\text{organic waste}})$$
(13.1)

 $N_{\text{fertilizer}}$ is the amount of N needed from fertilizers, manures, biosolids, etc.

 N_{crop} is the crop N requirement at realistic yield goal N_{soil} is the residual soil inorganic N (NH₄-N + NO₃-N) $N_{organic\ matter}$ is the N mineralized from soil organic matter $N_{previous\ crop}$ is the residual N available from previous legur

 $N_{\text{previous crop}}$ is the residual N available from previous legume crops

 $N_{\text{organic waste}}$ is the residual N available from previous organic waste use such as animal manures, biosolids, wastewater irrigation, etc.

In some cases, an N availability index, based on soil organic matter content, soil texture (indication of leachability and moisture holding capacity), and climate (indicated by crop being grown) is used to estimate soil N supplying capacity. Fertilizer N recommendations are adjusted accordingly with fine-textured soils with higher organic matter contents presumed to provide

more plant available N from mineralization and thus to need less fertilizer N. Mathematical models have also been developed to predict crop N requirements but with only limited success because of the amount of site-specific information required for the models to function with any degree of accuracy (Tanji, 1982).

Interpretations of N soil tests are done routinely and with reasonable success. However, soil N testing may be improved by use with plant analysis or other techniques now available to quantify plant N status in the field, such as remote sensing or leaf chlorophyll meters (LCMs). Plant N testing methods are discussed in Section 13.3; some environmental aspects of soil N testing are discussed in Section 13.2.7.3.

13.2.4.5 Soil Testing for Micronutrients (B, Cl, Cu, Fe, Mn, Mo, Zn)

Micronutrients are essential elements normally present in plants at very low concentrations (<100 mg kg⁻¹) and include boron (B), chlorine (Cl), copper (Cu), iron (Fe), manganese (Mn), molybdenum (Mo), and zinc (Zn). The following overview of micronutrient cycling focuses on soil properties and processes most relevant to soil testing and reflects the fact that four micronutrients exist in soils as cations (Cu²⁺, Zn²⁺, Fe^{2+,3+} and Mn²⁺) while three are found as an uncharged molecule ($H_3BO_3^0$) or anions [B(OH)₄-, Cl⁻, MoO₄²⁻].

Plant available Cu in soils originated from the weathering of igneous and sedimentary rocks. The main Cu bearing primary minerals are chalcopyrite (CuFeS₂), chalcocite (Cu₂S), and bornite (CuFeS₄). Soil total Cu concentrations typically range from 1 to 40 mg kg⁻¹ and concentrations in the soil solution are quite low, from 10⁻⁸ to 10⁻⁹ M. More than 99% of the Cu in the soil solution is found as Cu²⁺ complexed with organic matter; above pH 6.9 the dominant inorganic form of Cu is Cu(OH)₂⁰. Soluble Cu is in equilibrium with Cu complexed by organic matter, exchangeable Cu retained on the CEC sites of soil colloids, and Cu sorbed, occluded, or coprecipitated by soil oxides. Sorption of Cu by organic matter is the primary reaction controlling the plant availability of Cu although Cu solubility is also highly pH dependent, decreasing 100-fold for each unit increase in pH.

Plant available Zn in soils also originates from the weathering of igneous and sedimentary rocks and total soil Zn concentrations usually range from 10 to 300 mg kg⁻¹. The major Zn bearing minerals in soils include franklenite (ZnFe₂O₄), smithsonite (ZnCO₃), and willemite (ZnSiO₄). Zinc concentrations in the soil solution range from 2 to $70\,\mu g$ L⁻¹ (ppb) and Zn²⁺ is the major species below pH 7.7. Approximately 50%–60% of soluble Zn is complexed with organic matter. Plant available Zn also includes exchangeable Zn and Zn sorbed by clays, oxides, and carbonates. As with Cu, the solubility of Zn is highly dependent upon soil pH, decreasing markedly above pH 6.0–6.5 (Wear and Evans, 1968).

Iron is one of the major constituents of the earth's crust (~5%) and total Fe contents in most soils are quite high, ranging from 1,000 to 10,000 mg kg $^{-1}$. Major mineral forms of Fe include olivene ((Mg,Fe) $_2$ SiO $_4$), pyrite (FeS), siderite (FeCO $_3$), hematite (Fe $_2$ O $_3$), and goethite (FeOOH). Plant available forms of Fe include those that are sorbed by clays and organic matter. Soil solution

concentrations of Fe in equilibrium with these minerals are very low and depend greatly upon soil pH, ranging from 10⁻⁶ M in very acid soils to $<10^{-20}$ M in soils above pH 7.0. The form and solubility of Fe in the soil solution also depends upon soil redox potential; in well-aerated, oxidized soils, ferric Fe (Fe³⁺ or Fe(OH)₂+) predominates, while in reduced, waterlogged soils the major inorganic species is ferrous Fe (Fe²⁺). Each unit increase in pH decreases the solubility of Fe³⁺ by 1000-fold, but only decreases soluble Fe²⁺ by 100-fold. Of relevance to soil testing for Fe is the fact that the total concentrations of soluble inorganic Fe in most soils are too low to meet the nutritional needs of most plants, even under very acid soil conditions, yet plants are able to obtain adequate Fe for growth. Research has shown that natural organic compounds in soils (chelates) and exuded from plant roots play an important role in preventing the precipitation of Fe as insoluble compounds by forming Fe-chelate complexes that can move to plant roots by mass flow or diffusion. At the root surface, Fe dissociates from the chelate and is taken up by the plant.

Plant available manganese (Mn) in soils originates from the weathering of minerals such as pyrolusite (MnO₂), hausmannite (Mn₃O₄), manganite (MnOOH), rhodochrosite (MnCO₃), and rhodonite (MnSiO₃). Total soil Mn concentrations are from 20 to 3000 mg kg⁻¹ while soluble Mn is usually between 0.01 and 1.0 mg L⁻¹, existing primarily as Mn²⁺ in equilibrium with MnO₂ in oxidized soils and MnCO₃ in reduced soils. Exchangeable, sorbed, and organically complexed Mn are the forms important to plant availability. As much as 80% of soluble Mn in some soils is complexed with organic matter. Soil properties and processes affecting Mn solubility include soil pH, complexation/chelation, and redox potential. Manganese solubility decreases about 100-fold as pH increases by one unit and also increases markedly when soils become reduced and Mn oxides (e.g., MnO₂) dissolve.

Plant available boron (B) originates in most soils from the weathering of sedimentary rocks (e.g., shales) and tourmaline (a highly insoluble borosilicate mineral). Total soil B concentrations usually range from 2 to 200 mg kg⁻¹ with <5% available to plants. Unlike Cu, Zn, Fe, and Mn, which exist primarily as divalent cations, B in soils is found as undissociated $\rm H_3BO_3^0$ (pH 5–9) or as the B(OH)₄⁻ anion (dominant species at pH > 9.2). Major sources of plant available B in soils include those that are sorbed by soil clays and oxides or hydroxides of Fe/Al and the B complexed by organic matter. The uncharged nature of the $\rm H_3BO_3^0$ molecule makes it highly mobile in many soils, particularly those low in clays, oxides, and organic matter. However, B availability is well known to decrease at pH > 6.5–7.0 because of an increased affinity of soil clays and oxides for the B(OH)₄- anion.

Molybdenum is present in soils at very low levels, with total Mo values ranging from 0.2 to 5.0 mg kg⁻¹ and soil solution concentrations <0.5 μg L⁻¹. Plant available Mo is anionic in nature, existing in most soil solutions as $HMoO_4^-$ or $MoO_4^{2^-}$, species strongly sorbed by Fe/Al oxides under acidic conditions and/or complexed by organic matter. Unlike all other micronutrients, Mo availability increases with soil pH, due to the greater solubility of several Mo-bearing minerals at pH values >7.0 and to a decreased affinity of most soils for Mo.

Chloride occurs mostly in igneous and metamorphic rocks and, once weathered, is found in soils as precipitates and soluble salts such as NaCl, MgCl₂, and CaCl₂ and in the soil solution as the Cl⁻ anion. Dissolution of these salts is the primary process controlling Cl⁻ availability to plants. Soil solution concentrations of Cl⁻ vary widely as a function of soil type and geographic location, ranging from <0.5 to >6000 mg L⁻¹ in soils from arid regions. Chloride is very mobile in most soils, analogous in many ways to NO₃-N, and significant retention of Cl⁻ only occurs in highly acid soils that can develop positive, pH-dependent electrostatic charge on 1:1 clay or Al/Fe oxides.

13.2.4.5.1 Current Soil Testing Methods for Micronutrients

Soil tests for micronutrients have historically been conducted as special tests, restricted to situations where soil properties or crop characteristics indicated an economic response to micronutrient fertilization was possible. Consequently, for many years, and even today, separate soil tests were used for each micronutrient, or for groups of micronutrients with similar properties. However, the advent of multielement extractants, such as Mehlich 3, DTPA, and AB-DTPA, and of instruments capable of rapid, simultaneous analysis of soil extracts for several elements (ICP-AES) has increased the use of micronutrient soil testing in many areas of the world.

Soil sampling, handling, and storage for micronutrient soil testing are conducted following the standard techniques outlined in Section 13.2.3. Soil samples are almost always collected from topsoils (0-15 or 0-20 cm). The major consideration for micronutrients is the need to avoid contamination of the soil sample during sample collection, handling, and storage. For example, galvanized sampling tools and mixing buckets and some rubber stoppers contain Zn, metal surfaces on equipment used for grinding and sieving samples may contain Cu, Fe, and Zn, borosilicate glassware should be avoided during the extraction of B from soils as should the use of paper bags and boxes that may contain B in glues, and many common laboratory reagents contain Cl. Sample drying, the length and force of soil grinding, the speed of shaking during the extraction process, and the type of extraction vessel and soil:solution ratio have been shown to affect the quantity of extractable Cu, Fe, Mn, and Zn in some soils (Soltanpour et al., 1976, 1979). Given these somewhat unpredictable potential sources of error, following standardized methods for soil sampling, handling, preparation, and extraction is a vital aspect of micronutrient soil testing. Only a small amount of contamination or a slight alteration in procedure can badly skew a soil analysis, resulting in an erroneous recommendation.

Chemical extraction is the standard approach to assess micronutrient availability in soils. The major types of micronutrient soil tests used for Cu, Fe, Mn, and Zn are dilute acids and extractants that contain chelating agents. Less commonly used tests include neutral salts, which remove only small quantities of most micronutrient cations, and reducing agents, such as hydroquinone, used only for Mn (Table 13.4). In general, soil tests have been designed to remove soluble micronutrient forms

TABLE 13.4 Summary of Major Soil Testing Methods, Interacting Factors, and References for Micronutrient Soil Tests

Micronutrient	Soil Test and Critical Range	Comments and Interacting Factors Used in Soil Test Interpretation		
Boron ^a	Hot water: $0.1-2.0 \text{ mg kg}^{-1}$ Mehlich III: $0.7-3.0 \text{ mg kg}^{-1}$	Hot water is the most widely used method. Interacting factors include crop yield goal, pH, soil moisture, texture, organic matter, and soil type		
Copper	AB-DTPA: 0.5–2.5 mg kg ⁻¹ DTPA: 0.1–2.5 mg kg ⁻¹ Mehlich I: 0.1–10 mg kg ⁻¹ Mehlich III: 0.3–15 mg kg ⁻¹ 0.1 M HCl: 0.1–2.0 mg kg ⁻¹	AB-DTPA and DTPA are used for alkaline soils, Mehlich III for alkaline and acid soils, and Mehlich I and $0.1\mathrm{M}$ HCl for acid, low CEC soils. Interacting factors include crop type, organic matter, pH, and % $\mathrm{CaCO_3}$.		
Iron	AB-DTPA: $4.0-5.0 \text{ mg kg}^{-1}$ DPTA: $2.5-5.0 \text{ mg kg}^{-1}$	AB-DTPA and DTPA are used for alkaline soils (Fe deficiency is very rare with acid soils). Interacting factors include pH, % CaCO ₃ , CEC, organic matter, and soil moisture		
Manganese	AB-DTPA: 0.5–5.0 mg kg ⁻¹ DTPA: 1.0–5.0 mg kg ⁻¹ Mehlich I: 5.0 mg kg ⁻¹ at pH 6 10 mg kg ⁻¹ at pH 7 Mehlich III: 4.0 mg kg ⁻¹ at pH 6 8.0 mg kg ⁻¹ at pH 7 0.1 M HCl: 1.0–4.0 mg kg ⁻¹	AB-DTPA and DTPA are used for alkaline soils, Mehlich III for alkaline and acid soils, and Mehlich I for acid, low CEC soils. Interacting factors include pH, texture, organic matter, and $\%$ CaCO $_3$		
Molybdenum	Ammonium oxalate—pH 3.3: 0.1–0.3 mg kg ⁻¹	Soil testing for Mo is rarely done. Interacting factors are pH and crop		
Zinc	AB-DTPA: 0.5–1.0 mg kg ⁻¹ DTPA: 0.2–2.0 mg kg ⁻¹ Mehlich I: 0.5–3.0 mg kg ⁻¹ Mehlich IH: 1.0–2.0 mg kg ⁻¹ 0.1 M HCl: 1.0–5.0 mg kg ⁻¹	AB-DTPA and DTPA are used for alkaline soils, Mehlich III for alkaline and acid soils, and Mehlich I and $0.1\mathrm{M}$ HCl for acid, low CEC soils. Interacting factors are pH, % $\mathrm{CaCO_3}$, P, organic matter, % clay, and CEC

SSSA Book Series No. 3. SSSA, Madison, WI; Sims, J.T., and G.V. Johnson. 1991. Micronutrient soil tests, p. 427–476. In J.J. Mortvedt et al. (eds.) Micronutrients in agriculture. 2nd edn. SSSA, Madison, WI.

(including organically complexed) by solvent action, to displace exchangeable and sorbed forms by ion exchange and desorption reactions with other cations or with hydrogen ions (H_3O^+), to partially dissolve soil minerals or oxides that contain precipitated and occluded forms, and to dissociate or chelate micronutrient cations that are complexed by solid phases of organic matter. In most cases all four cations are extracted and analyzed simultaneously. The most common instrumental techniques used for micronutrient cations are AAS and ICP-AES.

Dilute acids (0.025–0.1 M) have been used for decades as soil tests for micronutrient cations, most successfully on acidic soils because they are not adequately buffered to extract sufficient quantities of micronutrients from calcareous soils. These extractants work primarily by dissociation, displacement, and partial acidic dissolution of cations from soil clays, oxides, and organic matter. The most common dilute acid soil tests today are the Mehlich 1 (dilute double acid: $0.0125\,\mathrm{M}\,\mathrm{H_2SO_4} + 0.05\,\mathrm{M}\,\mathrm{HCl}$) and $0.1\,\mathrm{M}\,\mathrm{HCl}$. The Mehlich 1 is a multielement extractant for macro- and micronutrients used in the southeastern and mid-Atlantic United States, and in South America. The $0.1\,\mathrm{M}\,\mathrm{HCl}$ soil test has been used for a wider range of soils, primarily as an extractant for Zn, Cu, and Mn.

The other major category of soil tests for micronutrient cations is extractants containing chelating agents, most commonly DTPA and EDTA. Chelating agents reduce the activity of free metal ions in the soil solution by forming metal-chelate

complexes, much as occurs in the rhizosphere of a plant. Replenishment of free ion concentrations in the soil solution (during the extraction process) by release from solid phases in the soil (clays, oxides, organic matter) occurs in response to the formation of the soluble metal-chelate complex. The amount of a micronutrient extracted by a chelate-based soil test therefore reflects both the initial quantity present in the soil solution and the ability of the soil to maintain that concentration. Chelatebased extractants thus simulate nutrient removal from the soil by plant uptake and replenishment of the soil solution by labile solid phases. Most chelate-based soil tests were developed for specific physiographic regions and soil types and are buffered at specific pH and ionic strength values to avoid the release of micronutrients from nonlabile solid phases in the soil. Hence, it is important to use them only for the soil type and conditions for which they were originally calibrated. For example, the DTPA soil test, commonly used for calcareous soils, is buffered at pH 7.3 and contains 0.01 M CaCl₂ to prevent the dissolution of carbonate minerals that might contain occluded or precipitated Cu, Fe, Mn, and Zn. Clearly, since the DTPA was developed for calcareous soils it would be inappropriate for highly acid soils without careful calibration and perhaps modification of the extractant composition (Lindsay and Norvell, 1978; Norvell, 1984; O'Connor, 1988). EDTA has been successfully used on a wide range of soils either alone or in multielement soil tests (i.e., 0.001 M EDTA is in the Mehlich 3 soil test and the modified Olsen soil test: 0.5 M

^a References: Hot water B, Berger and Truog (1940); Mehlich 3 B, Shuman et al. (1992).

NaHCO $_3$ + 0.01 M EDTA, pH 8.6) (Viro, 1955). Similarly, DTPA is included in the AB-DTPA extractant (1 M NH $_4$ HCO $_3$ + 0.005 M DTPA, pH 7.6) now widely used in the western United States.

Soil tests for the anionic or uncharged micronutrients (B, Mo, and Cl) have received less attention than those for micronutrient cations because of the relatively rare nature of crop response to fertilization with these elements. Most soil tests have focused on methods that remove soluble, sorbed, or organically complexed forms of these micronutrients.

The most common soil test used for B has been the hot water extraction method of Berger and Truog (1940) in which soil is boiled with water or 0.01 M CaCl₂, using a reflux condenser, removing soluble B and organically complexed B. Although shown to be a reasonably good predictor of plant response to B, the cumbersome, time-consuming nature of the Berger and Truog soil test has made its routine use difficult. Research by Mahler et al. (1984) using boiling plastic pouches, by Gestring and Soltanpour (1984) with the ammonium bicarbonate + DPTA soil test, and by Shuman et al. (1992) with the Mehlich 3 extractant has identified some practical alternatives to the original hot water method. Molybdenum is usually extracted with acid ammonium oxalate, primarily via a desorption reaction with the added oxalate, while deionized water or any dilute salt solution (e.g., 0.01 M Ca(NO₃)₂, 0.5 M K₂SO₄) can be used as a soil test extractant for Cl because of its high solubility in most soils.

Considerations in interpretation of micronutrient soil tests: Micronutrient deficiencies are, for the most part, associated with specific combinations of soil and plant factors that are reasonably well understood (Tisdale et al., 1993). Copper deficiencies are most common on soils that are extremely high in organic matter (peats, mucks) or with high pH, calcareous soils, while deficiencies with the other micronutrient cations (Fe, Mn, Zn) are almost always confined to calcareous or overlimed soils and sensitive crops. Boron deficiency is most frequently observed on sandy, low organic matter soils or following extremely dry periods that reduce the mineralization of organic matter and thus the release of organically bound B. Molybdenum deficiency rarely occurs except with very acid soils and then only with crops that are highly sensitive to low concentrations of soil Mo (e.g., legumes, crucifers, citrus). Chloride deficiencies are very unusual and confined to certain physiographic regions, such as the Northern Great Plains of the United States.

The critical value approach is the most widely used method to interpret the results of a micronutrient soil test (Tables 13.1 and 13.4). However, when micronutrient deficiencies are a definite concern, it has usually been shown that the predictive value of a micronutrient soil test can be improved by evaluation of more than one soil property or by knowledge of the crop to be grown. For instance, soil tests for Mn and Zn are much more accurate when soil pH is known; other examples of interacting factors that can improve soil test interpretation for micronutrients are given in Table 13.4. In some cases, quantitative "availability indexes," usually multiple regression equations based on the soil test result and another soil property, are calculated and used in place of the critical value approach.

Finally, several micronutrients can be toxic to plants if present in soils at high concentrations. The most common micronutrient phytotoxicities occur with Mn in highly acid soils (pH < 5.2) and B where only a slight over-application of fertilizer B can cause phytotoxicity. Although unusual, Cu and Zn can occasionally become phytotoxic in soils amended with agricultural, municipal, and industrial waste products, such as animal manures (pig and poultry), municipal biosolids, and some by-products of mining industries, if recommended or mandated management practices are not strictly followed (Sukkariyah et al., 2005). Critical phytotoxic levels based on micronutrient soil tests are much more difficult to establish than deficiency values and are usually highly specific to the plant that is grown and soil type.

13.2.5 Soil Testing Methods for Soil Chemical, Physical, and Biological Properties

The availability of essential and nonessential elements to plants, their potential to become phytotoxic, or to cause environmental problems via leaching, erosion, runoff, and/or volatilization depends upon soil physical, chemical, and biological properties. Some of these properties are routinely measured by soil testing laboratories; others are only measured on selected soil samples. Some are rarely measured at all but can be inferred from other soil properties or from information in USDA-NRCS Soil Survey manuals. Since the focus of this chapter is soil fertility evaluation, only the soil properties that are most relevant to plant growth are discussed (soil pH, lime requirement, organic matter, and soluble salts).

13.2.5.1 Soil pH

Soil pH is an index of the hydrogen ion activity in the soil solution that is in equilibrium with H retained by soil colloids (clays, organic matter, oxides) (van Lierop, 1990). It is a measure of the degree of acidity or alkalinity of a soil and is commonly measured electrometrically using a pH meter equipped with glass and reference electrodes (Thomas, 1996). Soil pH is one of the most useful pieces of information for soil fertility evaluation and management because it provides information on (1) the solubility, and thus potential availability or phytotoxicity of some plant nutrients and nonessential elements and (2) the relative biological activity of plants and soil microorganisms. The solubility of most micronutrients, and several nonessential trace elements (e.g., Cd, Ni, Pb) for plant uptake is highly pH dependent because the solubility of the solid phases containing these essential elements changes with soil pH. For most elements, solubility increases as the soil becomes more acidic; exceptions include P, which is most available at pH ranges between 5.5 and 7.5, and Ca and Mo, which are most available at higher pH values (pH > 7.0). Other processes important to nutrient and nonessential element retention in soils (e.g., cation exchange, sorption/desorption) also vary with pH. Acid soil infertility is most severe at pH values < 5.5 and is caused by the increased solubility and toxicity of aluminum (Al) and Mn and by the decreased plant availability of Ca, Mg, Mo, and P. Soil N availability is less under acidic

conditions because the bacteria responsible for mineralization of soil organic N are most active at neutral or slightly acid soil conditions. Alkaline soil infertility is most common in calcareous or overlimed soils and results from the reduced availability of several important nutrients including P, B, Cu, Fe, Mn, and Zn due to the decreased elemental solubility (P, Cu, Fe, Mn, Zn) or greater sorption (B) that occurs at higher pH values.

13.2.5.2 Lime Requirement

Soil pH is an index of the soil chemical environment and its general suitability for plant growth. Soil pH, however, provides no information on the amount of soil amendment needed to correct problems with acid or alkaline soil infertility. To determine the rate of lime (or acidulent) needed, it is necessary to measure the buffer capacity of the soil (ability of the soil to resist a change in pH). For acid soils, lime requirement is defined as the amount of agricultural limestone or other basic material needed to increase the soil pH from an unacceptably acidic condition to a value that is considered optimum for the desired use of the soil (Sims, 1996). The acidification requirement is similar to lime requirement and refers to the amount of acidulent (usually elemental sulfur or aluminum sulfate) needed to decrease soil pH to an optimum value. The lime requirement of a soil can be measured by a number of methods, but the most common is the use of soil-buffer equilibrations to determine "buffer pH" (Sims, 1996). A buffer pH measurement is conducted by adding a chemical solution buffered at a high pH (pH 7.5-8.0) to a soil sample, allowing the soil and buffer to equilibrate, and then measuring the pH of the soil-buffer suspension. The decrease in buffer pH that occurs when the acidity in the soil reacts with the buffered chemical solution is an index of the amount of soil acidity that must be neutralized by liming to adjust the soil to the desired pH. Field calibrations between buffer pH measurements and changes in soil pH upon liming are essential to the development of a buffer pH test. The most common buffer pH solutions in the United States are the Shoemaker-McLean-Pratt ([SMP], pH 7.5), the Adams-Evans ([AE] pH 8.0), and the Mehlich (pH 6.6). Recently, environmental and toxicity concerns about chromium and paranitrophenol, constituents of the SMP buffer, led Sikora (2006) to propose a modified SMP buffer. Chemicals chosen to replace chromium and p-nitrophenol were 2-(N-morpholino) ethanesulfonic acid monohydrate (MES) and imidazole. The new buffer is adjusted to pH 7.7. A study comparing soil-buffer pH with the new buffer versus the SMP buffer using 255 Kentucky and 87 soils from throughout the United States showed that the two methods were highly correlated ($r^2 > 0.97$). Similar concerns with the toxicity of paranitrophenol, exist for the AE buffer. Consequently, Sikora and Moore (2009) developed the Moore-Sikora (MS) buffer, which contains no hazardous chemicals and was shown to be highly correlated ($r^2 > 0.98$) with results from the AE buffer. The buffer has been successfully used by Clemson University (South Carolina) for 4 years but the authors suggest further field studies are needed prior to its widespread adoption in other regions of the United States. Another lime requirement technique involves extraction of exchangeable acidity or

exchangeable Al³⁺ from a soil with a salt solution (e.g., 2 M KCl), followed by titration of the extract with a standardized base. This is a rapid, inexpensive method that is well adapted to highly acidic, aluminous soils in areas with limited supplies of limestone. Application of sufficient limestone to neutralize 1.5–2.0 times the amount of exchangeable acidity is often adequate to eliminate some of the more serious limitations associated with acid soil fertility (e.g., Al toxicity). Finally, Liu et al. (2005) have shown success with a direct titration method to determine lime requirement based on an initial pH reading in 0.01 M CaCl₂ and a second reading following the addition of one dose of Ca(OH)₂, followed by extrapolation to the target pH. The more widespread availability of automatic titration systems suggests this approach should receive further investigation.

13.2.5.3 Organic Matter

The organic matter content of a soil is extremely important to soil fertility and many soil testing laboratories now include organic matter as a standard component in the routine soil test (which usually consists of pH, buffer pH, organic matter, and soil test extractable P, K, Ca, Mg). Soil organic matter is the nonliving organic material in the soil and includes both nonhumus (fresh plant, animal, and microbial residues) and humus (amorphous, highly stable, dark colored, organic material). Although organic matter is only a small percentage of most topsoils (1%-5%) and is present at very low levels in subsoils (<0.5%), consideration of organic matter in soil fertility evaluation is critical because it (1) provides plant nutrients, especially N, B, P, and S, as microorganisms decompose organic matter; (2) acts as a chelate, particularly important in maintaining micronutrient cations in a plant available form; (3) effectively complexes Al, reducing its phytotoxic effects in many soils; (4) has a high water holding capacity by weight and thus helps minimize the effects of moisture stress on plants; (5) is the predominant source of pH dependent CEC in most soils and thus contributes to the overall capacity of soils to retain nutrients and nonessential elements; (6) is a significant source of pH buffering, preventing marked and often undesirable changes in soil pH due to anthropogenic inputs; and (7) acts as an aggregating agent, cementing smaller soil particles together and thus improving soil structure, resulting in better aeration and more prolific root growth. Despite the many important roles soil organic matter plays in soil fertility, only recently soil testing laboratories have begun to measure and routinely report this soil property. The long-standing, traditional approach used to estimate soil organic matter content was to measure organic carbon (C) by wet chemical oxidation using dichromate $(Cr_2O_7^{2-})$ as the oxidant. Soil organic matter was then calculated from an empirically derived relationship between organic matter and organic C. This method was too time consuming to use on a routine basis and also generated a significant amount of high Cr waste; hence, it was primarily used as a special test. Most soil testing laboratories now estimate soil organic matter content by the "losson-ignition" (LOI) method in which a soil sample is "ignited" in a high temperature oven at ~360°C-400°C for several hours or overnight. The weight loss upon ignition is assumed to be proportional to soil organic matter content. Usually, an empirical relationship between LOI and some direct measure of organic matter (e.g., dichromate oxidation) is used to calculate estimated organic matter content. The LOI method is well suited to modern soil testing laboratories that wish to include an estimate of soil organic matter content in the routine soil test. Advances in electronic weighing and data acquisition and processing have resulted in LOI becoming an efficient, reasonably accurate approach to estimate soil organic matter.

13.2.5.4 Soluble Salts

Soil salinity, defined as the presence of excessive levels of dissolved inorganic solutes in the soil solution, is a global problem and directly affects soil fertility. Soils high in soluble salts, either naturally or due to inputs of salts in fertilizers and irrigation waters, can negatively affect plant growth in several ways. Specific ion toxicities can occur, particularly if high concentrations of Na, Cl, and B are present, causing direct injury to plants, especially young seedlings. Saline soils also disrupt plant water relations by decreasing the osmotic potential of the soil solution, thus making it more difficult for plants to extract water from soils, even to the point of causing plant injury and death. Measuring soluble salts is a fairly easy task but is usually done as a special test even in arid regions where soil salinity is a common problem. Rapid tests for soluble salts are done by measuring the electrical conductivity of a soil:water extract at a 1:2 or 1:5 soil:solution ratio. A more time consuming test, but one that better represents the soluble salts concentration in the soil solution is the saturated paste extract, obtained by mixing soil and deionized water to the point of saturation, followed by filtration and analysis of the extract for electrical conductivity.

13.2.6 Soil Testing: Interpretation and Recommendations

Interpretation is a systematic process, relying primarily on statistical evaluation of research comparing soil test parameters with plant performance, or other indexes of the success of a land use program. Recommendations arising from soil test interpretation must not only be quantitative in nature but also include professional judgment since it is not possible to identify all the factors that control plant performance from analysis of a single soil sample. Individuals responsible for nutrient management recommendations must be thoroughly familiar with the process of soil testing and with all aspects of the intended land use, including soil types, plants to be grown, climate, crop management practices, and any economic or environmental factors that may restrict a recommendation.

13.2.6.1 Correlation and Calibration of Soil Tests

Interpretation of soil analyses begins with soil test correlation, defined as "...the process of determining whether there is a relationship between plant uptake of a nutrient or yield and the amount of nutrient extracted by a particular soil test" (Corey, 1987). To be of value, a soil test must first be shown by laboratory,

greenhouse, and field research to be statistically correlated with some measure of plant performance. Greenhouse studies are usually the first step in soil test correlation and can rapidly and inexpensively assess the potential value of a soil test for widely differing soils and plants. The standard approach is to obtain samples of soils representative of the range of soil types where the soil test will be used, measure the amount of soil test extractable nutrient (or nonessential element) in each soil, grow plants in the soils under controlled greenhouse conditions, where moisture, light, and spatial variability are minimized, and then measure plant yield and elemental composition. Statistical correlation and regression methods are then used to assess the relationship between soil test level and plant response. Correlation analysis determines if the change in plant yield or nutrient composition is proportional to the amount of nutrient extracted by a soil test. If a high degree of correlation exists, regression analysis will provide a predictive equation that reliably estimates plant yield or elemental composition at each soil test value. In some cases, multiple correlation and regression analysis are used to develop a predictive equation that quantifies the relationship between plant performance and more than one soil property (e.g., soil test value and pH, organic matter, texture, etc.).

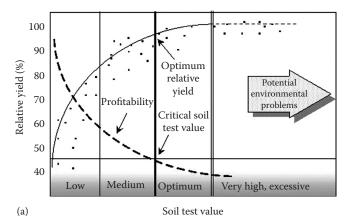

If a soil test is significantly correlated with plant performance in the well-controlled greenhouse environment, field experiments are then conducted to determine how accurate the test will be under normal growing conditions. For greatest reliability, field trials should be conducted at many locations with a range of soil types and soil test values for the nutrient of interest. The trials should be done for several years and should include multiple rates of the nutrient being investigated. Experiments should be replicated at least three times and other variables besides the nutrient being studied that affect plant performance should be controlled to the extent possible (e.g., using irrigation to minimize soil moisture stress, pesticides to prevent insect damage and weed competition, and fertilization or liming to ensure that other nutrients do not limit plant growth and yield). Correlation analysis is again used to determine if there is a statistically significant relationship between the soil test value for a nutrient and plant response. Field experiments usually have poorer correlation coefficients than greenhouse studies because (1) they are conducted at fewer locations due to the time and expense required, and (2) uncontrolled variability is usually present that affects the soil test-plant performance relationship in an unpredictable manner. Recently, the costs and time required to conduct field and greenhouse studies have caused a greater reliance on laboratory correlation studies as a means to evaluate new soil test extractants. For example, several laboratory studies have compared the Mehlich 3 multielement soil test with earlier soil tests (Hanlon and Johnson, 1984; Wolf and Baker, 1985; Sims, 1989). Many of these studies reported highly significant correlations between nutrients extracted by Mehlich 3 and those extracted by the Mehlich 1, Bray P₁, 1 M NH₄OAc, and EDTA, indicating that the Mehlich 3 could be as reliable a means to evaluate soil fertility as the existing soil test. However, while laboratory-based correlation studies may be acceptable for the preliminary evaluation

of new soil tests, they should not be used as the sole means to determine soil test reliability. It is fundamental to soil test correlation that the amount of an element extracted by the soil test be correlated with what is of actual interest, usually plant yield or elemental composition (Fixen and Grove, 1990).

The next step in soil test development is calibration, defined as "...ascertaining the degree of limitation to crop growth or the probability of a growth response to applications of a nutrient at a given soil test level" (Dahnke and Olson, 1990). The purpose of calibration studies is to categorize soil test levels in terms of the probability of economic response to applications of a nutrient or for their potential to affect the environment. Traditionally, soil test results have been categorized as very low, medium, high, and very high. More recently, the terms "optimum" and "excessive" have been used to describe soil nutrient status and some regions, such as the northeastern United States have identified two separate classes of soil test category—"crop response" and "environmental impact" (Beegle, 1995). Tisdale et al. (1993) suggested that probability of an economic response to fertilization with P and K for a soil rated as "low," "medium," "high," and "very high" in either nutrient would be 70%-95%, 40%-70%, 10%-40%, and <10%, respectively. Several of the more important approaches used in soil test calibration are briefly described below; for a more thorough review of this subject, refer to Dahnke and Olson (1990) and Black (1993).

The calibration process is essentially an effort to mathematically model the relationship between soil test level and plant response to nutrient additions, which is almost always nonlinear. Consequently, curvilinear regression models (exponential, quadratic, quadratic-plateau) are often used to identify the point where plant performance is optimal (e.g., the plateau yield, usually associated with 93%-95% of maximum attainable yield) and then to determine the soil test value associated with optimum yield, which is referred to as the critical level or critical value (Figure 13.3a). Curvilinear models are often based on relative yield or percent yield, defined as the yield obtained without addition of the nutrient being studied divided by the yield attained at that location when no other factors are limiting. Relative yield data from field trials in the region of interest are combined and plotted against the soil test value from the control treatment for each trial and the critical level is determined mathematically or graphically. Use of relative yields minimizes the influence of uncontrolled variables and allows for more effective interpretation of data collected over many different years, locations, soils, climates, and management settings. Once the critical value has been identified, soil test values below this level are subdivided into categories that are associated with the probability of crop response (e.g., low, medium, optimum) and the nutrient rate required for an optimum yield. It is important to note that critical soil test levels may vary between soils, crops, and climatic regions and will usually differ between soil test extractants. For instance, critical soil test P values by the Bray P₁ Olsen, Mehlich 1, and Mehlich 3 soil tests are about 30, 12, 25, and 50 mg kg⁻¹, respectively (Jones, 1999).

Another calibration approach used to identify critical soil test levels is the Cate-Nelson method (Figure 13.3b; Cate and

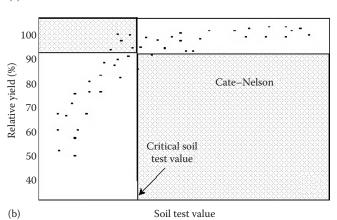

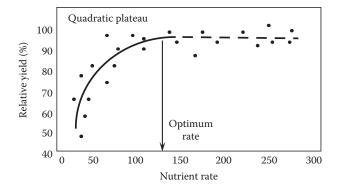

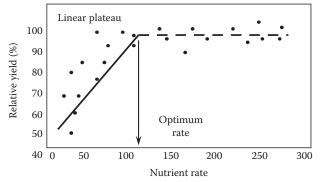

FIGURE 13.3 Generalized illustration of the principles of soil test correlation and calibration using (a) curvilinear models and (b) the Cate–Nelson approach.

Nelson, 1965). In this approach, relative yield is plotted against soil test value and the data are subdivided graphically into four quadrants either visually, using professional judgment, or mathematically (Nelson and Anderson, 1977) by placing a horizontal line at the optimum relative yield (93%–95% of maximum yield) and a vertical line at the soil test value that minimizes the number of points in the upper left and lower right quadrants. If the soil test under consideration is reliable, there will be few points in the upper left or lower right quadrants. Points in the upper left quadrant would mean that a low soil test value was associated with a high relative yield; points in the lower right quadrant are those where a high soil test value was associated with a low yield. Both of these are inconsistent with the basic premise of soil testing, that is, a soil test can accurately and reliably separate responsive from nonresponsive sites. If most points are in the lower left or upper right quadrants, then the soil test accurately predicts plant performance, that is, low soil tests have low relative yields and high soil tests have high relative yields.

As shown in Figure 13.4, the mathematical approach used to model the relationship between plant performance (relative yield) and rate of nutrient added can affect the determination of the economically optimum nutrient rate. Thorough discussions of the mathematical models used to interpret soil test results are provided by Black (1993).

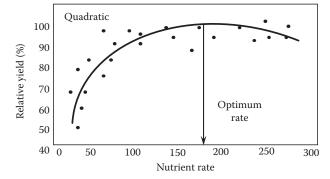

FIGURE 13.4 Illustration of the influence of type of mathematical model selected on the identification of the nutrient rate required for optimum yield.

13.2.6.2 Recommendation Philosophies for Soil Test Interpretation

The final phase in soil test development is the recommendation process in which the actual amount of nutrient to be applied, the application method, and the timing of the application are specified in detail. Individuals making a nutrient recommendation must integrate the quantitative information from soil test calibrations (e.g., the probability and magnitude of response likely to occur at a given soil test value of the nutrient) with other, more subjective aspects of nutrient management. Individuals skilled at making efficient recommendations are able to combine soil testing information with their professional experience, judgment, and scientific understanding of the system of interest in a manner that optimizes the profitability of nutrient use while minimizing any potential impacts on environmental quality. Given the subjective nature of this process, it is not

surprising that several different recommendation philosophies have evolved and now receive widespread use. The two most common philosophies, for agricultural crops, are "rapid build-up and maintenance" and "sufficiency level." Both philosophies are more commonly used with "immobile" plant nutrients, those that do not readily leach from topsoils or the root zone (P, K, Ca, Mg, Cu, Fe, Mn, Mo, Zn), than with "mobile" nutrients (B, Cl, NO₃-N, SO₄-S) where more comprehensive soil test approaches, such as subsoil testing, must be relied upon.

The rapid build-up and maintenance approach recommends that soil fertility be built to an optimum level as rapidly as possible, usually within 2 years. Following this initial "build-up" of soil fertility, "maintenance" nutrient applications are made annually at rates equal to the amounts removed in the harvested portion of the crop. This philosophy is sometimes referred to as "fertilization of the soil" and proceeds somewhat independent of soil testing since nutrient applications are made each year, regardless of soil test results. As noted by Dahnke and Olson (1990), "...the rapid build-up and maintenance concept discounts the inherent nutrient delivery capacity of a soil's native mineral reserves which, with most soils other than sands is large for most nutrients" and "Complete adherence to this system... would eliminate the need for further soil testing." While still used, economic and environmental questions about the appropriateness of this recommendation philosophy persist (Olson et al., 1987).

The most widely used recommendation philosophy today is the "sufficiency level" approach, which "...promotes the idea that a measurable soil test level exists below which responses to added fertilizer are probable and above which they are not" (Eckert, 1987). This approach is also sometimes referred to as "fertilization of the crop" and is a more conservative approach than rapid build-up and maintenance because nutrients are only recommended when soil test values are below the critical soil test level and are applied proportionate to the soil test category (i.e., more nutrients are added to soils that are rated low than those that are rated medium). The sufficiency level approach also inherently includes a build-up phase, but once soil fertility is in the optimum range, nutrient additions cease, or are minimal, until subsequent soil testing indicates that soil fertility has declined to the point where an economic response to further nutrient inputs is likely. There is no evidence to support the contention that the sufficiency level approach causes unnecessary depletion of soil nutrient reserves; in fact most studies have shown that adhering to this philosophy results in a slight buildup of soil fertility. Consequently, most soil test calibration research supports the use of the sufficiency level concept for soil test recommendations.

13.2.7 Environmental Soil Testing

13.2.7.1 Overview of the Principles and Purposes of Environmental Soil Tests

Soil testing has traditionally been used to evaluate the soil limitations to agronomic crop performance imposed by nutrient deficiencies (or pH, soluble salts, etc.) and to guide the recommendation process so that these limitations could be eliminated

economically and without impacting the quality of our environment. In recent years, interest has grown in environmental soil testing, defined here as "quantitative analysis of soils to determine if environmentally unacceptable levels of nutrients, nonessential elements or organic compounds are present." Environmental soil testing is a much more ambiguous process than agricultural soil testing because it is usually quite difficult to quantify the meaning of the term "environmentally unacceptable." Absent a clear, quantitative measure of success, such as crop yield for agricultural soil testing, the entire process of soil testing, from sample collection to recommendation, becomes more diffuse and more complex. Nevertheless, the rising interest in environmental protection in many areas of the world has prompted an increased effort to use soil testing as an index of the risks posed by soils to other sectors of the environment, particularly ground and surface waters. Given this, it is appropriate to consider the most effective means to restructure soil testing practices to meet environmental goals (Sims et al., 1997).

In the broadest sense, the goals of environmental soil testing are the same as those of routine, agricultural soil testing—rapid, accurate, and reproducible soil analysis by the most appropriate methods, and a reasonable interpretation of results related to environmental risk. Factors to consider when developing an environmental soil testing program are discussed next, using two reasonably common examples, potentially toxic trace elements and plant nutrients that are known to degrade water quality. In both cases, it is critical to consider the conceptual differences in interpretation of an environmental soil test, illustrated in Figure 13.5, compared to an agricultural interpretation (Figure 13.3).

13.2.7.2 Soil Testing for Potentially Toxic Trace Elements

Soil testing for potentially toxic trace elements is an environmental issue because some plant nutrients (Cu, Mo, and Zn) and nonessential elements (As, Cd, Cr, Hg, Ni, Pb, Se) have been shown to be toxic to either plants, animals, or humans. Soils may contain naturally high concentrations of one or more of these elements (very unusual), or concentrations may increase as a result of some anthropogenic activity such as the intentional addition of wastes as beneficial soil amendments (e.g., animal manures, municipal sewage sludges, industrial by-products). Some soils may be highly polluted with toxic elements due to mismanagement of potentially beneficial wastes, by an accidental spill or discharge, or as a result of an industrial activity such as mining or smelting. Note that contamination and pollution are not the same. Contamination occurs when a substance is present at concentrations higher than would occur naturally but no adverse effect on an organism is apparent while pollution implies not only an elevated concentration in the soil, but clearly documented adverse effects on some organism (Pierzynski et al., 1994).

Soil testing for potentially toxic trace elements begins with an understanding of the nature of the risk involved—what organisms may be affected, by what pathway, and by which elements. Primary areas of concern in general are direct soil ingestion,

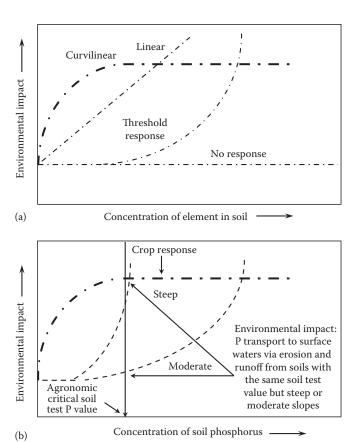

FIGURE 13.5 Illustration of points to consider in interpretation of environmental soil tests. As seen in (a) increasing the concentrations of soil nutrients or nonessential elements can induce no environmental response, cause a response once a threshold is reached, or have a linear or curvilinear effect on the environmental parameter of interest. In (b) crop response to increasing soil concentrations of a nutrient is contrasted with the environmental impact of that element, which can be modified by other soil properties. For example, crop response to inputs of phosphorus (P) is normally curvilinear, while the impacts of P on surface waters due to erosion and runoff can follow a threshold response. Soils with the same soil test P value, but varying slopes (steep or moderate) will have differing environmental impacts. (Figure a adapted from Pierzynski, G.M., Sims, J.T., and Vance, G.F. 1994. Soils and environmental quality. Lewis Publishers, CRC Press, Boca Raton, FL.)

phytotoxicity, plant uptake and food chain contamination, and water pollution from erosion, runoff, or leaching. Direct soil ingestion is normally only a concern for Pb and with young children who are most likely to ingest soil or inhale dust from high Pb soils. Phytotoxicity is rarely an issue with Pb except in highly polluted soils at industrial sites but is a greater concern with Cu, Cr, Ni, and Zn. Food chain contamination and human health effects are most often associated with Cd and Hg and water quality concerns with As, Cu, Hg, and Se. Knowledge of the nature of the risk and the element of concern helps to determine the most effective soil sampling protocol. In the case of Pb in urban soils where human health is the concern, it may be advisable to collect very shallow soil samples (<2 cm) since this is the soil depth most likely to be ingested. A similar depth would be useful if

runoff or erosion were the issue since rainfall primarily interacts with only the uppermost few cm of the soils. However, if concerns exist about ground water pollution, sampling into subsoil horizons, perhaps to a depth of 1-2 m would be recommended to determine if elemental leaching is occurring. For elements where the main concern is phytotoxicity and food chain contamination, the normal sampling depths associated with the crops to be grown are usually acceptable (e.g., 0-20 cm). If remediation of the site is the goal, either by soil removal, soil washing, or soil amendment, then systematic deep sampling (e.g., 0-5, 5-10, 10-20, 20-40, 40-60, 60-100 cm) is recommended to determine the depth of soil contamination and thus the extent of remediation required. Careful consideration should also be given to the soil sample handling and preparation steps to avoid contamination from any sampling and mixing tools or grinding and sieving devices (e.g., stainless steel, used in many electric grinding device contains Cr and Ni) and to protect the health and safety of the individual taking the sample. The method of analysis to be used varies with the intent of the test. If the goal is to assess biological availability (e.g., plant uptake, human ingestion) then many dilute acid or chelate-based soil test extractants, or the PBET mentioned earlier (Section 13.2.2.1) may be suitable, providing due consideration is given to the most appropriate test for the intended land use or human health concern (O'Connor, 1988). Interest, and field research, using the PBET has increased in recent years as the need to remediate metal-contaminated sites has grown. Areas of particular interest are simplifying the methodology to adapt the PBET for routine testing and standardizing the interpretation of PBET results. For example, Fendorf et al. (2004) simplified the PBET method by reacting 0.5 g soil and 50 mL of 1 M glycine, adjusted to pH 3 for 1 h in a 35.6°C water bath. They found this method accurately tracked decreases in bioaccessibility of As, Cr, and Pb in a wide range of surface and subsoils from the United States. Other simplifications of the PBET have been evaluated by Yoon et al. (2007) in studies of method to immobilize Pb and reduce leaching, by Brown et al. (2007) in research on the use of soil amendments to reduce Pb bioavailability at a U.S. Environmental Protection Agency (USEPA) Superfund site, by Brown et al. (2003) in studies of factors controlling Pb bioavailability in urban soils, and by Moseley et al. (2008) in investigations of the use of phosphate soil amendments to reduce Pb bioaccessibility in industrial and firing range soils. However, if the goal is to quantify the extent of accumulation of an element, relative to normal soils or natural background levels, or to monitor this accumulation over time, methods that determine or approximate total elemental content are recommended. One example is USEPA Method 3050 that successively digests a soil sample with concentrated HNO3 H₂O₂, and HCl to measure "total sorbed metals" by acidic dissolution of clays, oxides, and carbonates and oxidation of organic matter; elements associated with silicates are not dissolved. Therefore, for a true measure of total elemental content of a soil sample, complete digestion of the soil with strong acids (e.g., HNO₃-HClO₄ for Cd, Hg, and Pb), by carbonate fusion (Cr, Ni), or by alkaline oxidation techniques (As, Se) is required. Given

the costs and difficulty of measuring total elemental content of trace elements in soils it is often advisable to use rapid soil testing methods as surrogate monitoring techniques (Sims and Johnson, 1991).

Interpretations and recommendations for soil tests for potentially toxic trace elements are considerably more difficult than for agricultural systems and are often very site and element specific. As mentioned above, the main difficulty lies with soil test calibration—establishing a quantitative relationship between an agreed upon measure of environmental risk and the amount of an element measured by the soil test. In most cases, this has been done by the use of complex risk assessment models that first identify the "target organism" of concern (e.g., human vs. plant) and then evaluate all possible pathways by which the target organism may be exposed to the risk factor (the toxic trace element). If possible, a "most sensitive pathway" is identified, defined as the lowest soil concentration level at which an adverse effect on the organism would be likely to occur (e.g., soil ingestion vs. consumption of contaminated drinking water). Regulatory upper limits may then be established for that pathway, which can be monitored by the soil testing methods described above. This approach was used by USEPA in the formulation of the national rule for the disposal and utilization of municipal sewage sludges, which established regulatory limits for the total amount of several trace elements that could be applied to agricultural soils via land application of these sludges (Ryan and Chaney, 1993). Additional information on the methods used to interpret soil testing results is found in U.S. Environmental Protection Agency (1989), Risser and Baker (1990), and Pierzynski et al. (1994).

13.2.7.3 Soil Testing for Plant Nutrients with Water Quality Impacts

Soil testing for plant nutrients that can degrade water quality is focused primarily on N and P because of their well-documented effects on ground (N) and surface (N, P) water quality. The principles, practices, and problems of soil testing for N were described in Section 13.2.4.4. Other than the methods described in that section (e.g., the PSNT and ISNT), which focus on identifying sites with an adequate N supply and thus avoiding unnecessary applications of fertilizers or organic sources of N (manures, sludges), there are no other approaches currently available for use in an environmental soil testing program for N. Environmental soil testing for P, however, is a considerably different matter. Growing international concerns about the role of P in the eutrophication of surface waters stimulated a large research effort on environmental soil testing for P beginning in the late 1980s and continuing even today. The focus of this effort has been the use of soil testing alone, or as a component of site indexes and nonpoint source pollution computer models, to identify soils that are most likely to be significant nonpoint sources of P pollution of streams, rivers, ponds, lakes, and bays. Some aspects of environmental soil testing for P are described below, illustrating the changes needed in soil sampling, analysis, and interpretation when surface water protection, not agricultural production, becomes the primary goal. Readers are

referred to several reviews for more detailed information on this topic (Sims, 1993; Sharpley et al., 1996; Sibbesen and Sharpley, 1997; Sims, 1997; Tunney et al., 1997; Maguire and Sims, 2002).

13.2.7.3.1 Establishing Upper Critical Limits for Soil P Using Soil Testing Methods

One approach proposed for environmental soil testing for P is to simply establish an upper critical limit for soil P using currently available agronomic soil testing methods (e.g., Bray P₁, Mehlich 1, Mehlich 3, Olsen P). Soils that exceeded the upper critical limit for soil test P would no longer receive P inputs from any source (e.g., fertilizers, manures, biosolids) and would be targeted as priority areas for soil and water conservation practices to prevent P loss in erosion, runoff, and leaching. Two reasons are usually given to justify the need for this upper critical limit. First is that an extensive body of research shows that soils that are overfertilized with P relative to crop requirements will create an increased risk of nonpoint source pollution of surface waters (Sharpley, et al. 1994; Sims et al., 1997, 1998, 2002; Tunney et al., 1997). Second is the concern that continuing to apply P to soils well beyond values that are needed for crop production contradicts the principles of sustainable development and sustainable agriculture. The rationale underlying this second concern is the fact that P is obtained from a finite natural resource base, at a cost to society, and that agricultural practices that waste this resource are inconsistent with sustainability. Despite these concerns, until recently there was a reluctance to establish upper critical limits using soil test P measurements primarily because (1) agronomic soil tests were not originally designed or calibrated for environmental purposes and thus there was uncertainty concerning their accuracy at identifying soils with the potential to contribute environmentally significant amounts of P to waters by runoff or leaching and (2) there would be an unjustified reliance upon agronomic soil test P alone by environmental regulatory agencies attempting to control nonpoint source pollution of surface waters, ignoring the complex interaction between soil P and the transport processes and soil/crop management factors that control the movement of P from soil to water.

Because of these questions and concerns, the most appropriate means to use existing agronomic soil P tests, or new soil test methods, to identify soils with a high risk of P transfer to water has received intense research interest in the past decade. Results of many laboratory and field studies conducted in the 1990s and 2000s have clearly shown that agronomic soil P tests are often well correlated with other measures of soil P that suggest increased risks of P loss, such as water soluble P, the equilibrium P concentration in the soil solution (EPC₀), easily desorbable P (e.g., P extracted by Fe-oxide filter paper strips), and algal-available P (Gartley and Sims, 1994; Sibbesen and Sharpley 1997; Sims 1997; McDowell and Sharpley, 2001; Vadas et al., 2005). Additional studies of the relationships between agronomic soil test P and dissolved P concentrations in overland flow or leachate provided direct evidence for increased risks of P loss from overfertilized soils (Heckrath et al., 1995; Westermann et al., 2001; Maguire and Sims, 2002; Little et al., 2007). In some cases, this relationship was near-linear, while in others there appeared to be a "change point" above which there was a more rapid increase in dissolved P concentrations in runoff or leachate with increases in soil test P. Research has also shown that maintaining soil test P in the optimum range for plant growth minimizes dissolved P losses. When combined with information on soil erosion, soil test P can also be used to assess the risk of particulate P loss to water, as is done by risk assessment tools such as the P Site Index, as discussed below.

"Environmental soil P testing," however, is not confined to the use of agronomic soil P tests. It may mean the use of completely different methods for soil sampling, analysis, and interpretation than those done for agricultural purposes. Or, it may mean that an environmental or regulatory interpretation is now being applied to results of an agronomic soil P test, such as establishing an upper limit for soil test P beyond which no further P additions can be made. Changes in soil sample collection may include sampling to a shallower depth (0-5 cm) if overland flow is of greatest concern or to the depth of the mean high water table (e.g., 50-150 cm) if P leaching and subsurface flow is the main pathway for P loss. Different analytical methods may be used such as assessment of the degree of soil P "saturation" (DPS), water-soluble P, easily desorbed P, "algal available" P, and quick tests for P sorption capacity. For example, a DPSox method based on acid ammonium oxalate extraction of P, Al, and Fe was developed in the Netherlands to identify soils where P leaching to shallow groundwaters is a risk. Oxalate extractable P (Pox) represents the amount of P currently sorbed by the soil and oxalate Al and Fe (Alox, Feox) are proportional to the P sorption capacity of noncalcareous soils. The molar ratio of Pox to $[\alpha \text{ (Alox, + Feox)}]$ is thus an indication of soil P saturation (where α is a parameter used to convert (Alox + Feox) to estimated soil P sorption capacity and typically ranges from 0.4 to 0.6). Upper limits for DPSox of 25%-40% are most commonly used today. Research has found increases in water-soluble and desorbable P in soils above these DPSox values, suggesting a greater risk of P loss to surface waters and shallow groundwaters from P-saturated soils. Research has also shown that DPS measured by the Mehlich 3 (M3) soil test is well correlated with DPSox and also with P concentrations in leachate and overland flow (Sims et al., 2002). The Mehlich 3 soil P test is widely used in the United States and Canada, and some soil testing laboratories now report a soil P fertility assessment (M3-P) and soil P saturation (M3-DPS) using one soil extraction. In addition to using soil P saturation to predict dissolved P losses, research has also shown that using the "safe P storage capacity" (SPSC) of a soil can be accurately estimated using Mehlich 1 or Mehlich 3 DPS values (Nair and Harris, 2004; Chrysostome et al., 2007). The SPSC concept is used to determine how much additional P loading can occur before dissolved P losses become an environmental concern, particularly important in settings where manures or biosolids are regularly applied to soils.

With the possible exception of the M3-DPS test, environmental P tests would probably not be conducted on every sample submitted as part of a nutrient management plan. Instead, they

would be part of a more intensive testing procedure used when agronomic soil test P values were considered high enough to warrant further investigation. Even more important, most soil scientists recommend that environmental soil P tests not be used alone, but as a component of a more holistic risk assessment process, such as the P Site Index (Heathwaite et al., 2005) a risk assessment tool that integrates soil P with P transport and management practices to characterize the potential for P loss at a site. For instance, the states of Delaware and Maryland in the United States require that a P Site Index be conducted for fields with an agronomic soil test P (Mehlich 3) value >150 mg P kg-1. Nearly every state in the United States has developed and adopted a P Site Index as the preferred means to assess the risk of P loss from agricultural fields to surface waters, as opposed to the use of a soil P test alone. Many P Site Indices are now available on the internet, such as a very comprehensive index developed by the University of Wisconsin (see http://wpindex.soils.wisc.edu/).

13.3 Plant Testing

Soil fertility evaluation does not rely upon soil analysis alone. Many techniques now exist to assess soil fertility by characterizing the growth and elemental composition of plants. These include visual diagnosis, in-field evaluation techniques, laboratory analysis of plant tissues, and remote sensing. Plant analysis includes both rapid in-field tissue testing and total elemental analysis of plant samples, normally conducted in the laboratory. In both cases, the underlying premise is that the plant concentration of an element is proportional to the availability of the nutrient in the soil and thus is an index of soil fertility. Visual diagnosis and remote sensing do not actually determine the nutrient concentration in a plant, but instead rely upon changes in plant color or growth as indexes of soil fertility.

13.3.1 Visual Diagnosis of Deficiency Symptoms

With experience it is possible to identify visual symptoms that result from nutrient deficiencies. Examples include severely stunted growth and purpling of older leaves (P), chlorosis and necrosis of leaf margins (K), interveinal yellowing of newer leaves by Fe and Mn and of older leaves by Mg, and distorted meristems and blackened internal tissues (B). In general, visual diagnosis should be verified by soil and plant analysis, prior to taking corrective actions. Tisdale et al. (1993) cited four reasons for this: (1) the symptom may be caused by a deficiency of more than one nutrient; (2) the deficiency of one nutrient may be caused by an excess of another; (3) other factors, such as insect and disease injury, can create symptoms similar to nutrient deficiencies; and (4) the symptom may be caused by more than one growth factor (e.g., P deficiency can occur in cold, wet soils that have optimum P fertility levels—the deficiency disappears when soils warm). Other factors to consider are the fact that the same symptom may be caused by different nutrients in differing plants. For example, purpling of older leaves, typically due to P,

can be caused in cruciferous plants by S deficiency. The location of a deficiency on the plant can assist in proper identification of the cause. Nitrogen and S can both cause yellowing of plant leaves; however, because N is more mobile in most plants than S, its deficiency symptoms usually occur on older leaves, while S deficiencies are seen as a more overall yellowing. Calcium and most micronutrients (B, Cu, Fe, Mn, Zn) are rather immobile in plants; hence, their deficiencies usually occur on new growth, compared to some of the more mobile macronutrients (N, P, K, Mg) where deficiency symptoms are observed on older plant parts. Finally, for many plants, by the time a nutrient deficiency symptom can be accurately diagnosed, it is either too late for corrective action (unless nutrients can be added via fertigation or sidedressing) or unwise because the deficiency has already damaged the plant beyond the point where nutrient additions can profitably correct the problem.

13.3.2 In-Field Evaluation of Plant Nutritional Status

In addition to visual diagnosis, there are several "in-field" diagnostic techniques that can be used to provide semiquantitative information on plant nutritional status. The most common is the use of rapid tissue testing kits for the colorimetric analysis of plant sap. The color that develops after addition of the appropriate chemical reagents to sap is proportional to the concentration of the nutrient (usually only N, P, and K are tested in these kits). The entire process takes only a few minutes much less than required for total elemental analysis of a plant tissue by an analytical laboratory, which can require a week or more. In general, because of its semiquantitative nature, rapid tissue testing should only be used as a guide, and not as the sole basis for nutrient management recommendations. Tisdale et al. (1993) also cautioned that rapid tissue testing must (1) only be done with the correct plant part, sampled at the proper time of year and, for some nutrients (e.g., NO₃-N), at the proper time of day because nutrient concentrations change during the day; (2) be done in a comprehensive manner, continuing the testing throughout the growing season, not as a one-time activity; (3) focus on periods of maximum vegetative growth and reproductive stages to best assess a fertilizer program; (4) be the average value from the analysis of at least 10-15 plants and be collected from areas of normal and deficient plant growth.

One advance in field-scale plant N testing is the LCM, a small, hand-held spectrometer that directs a beam of light corresponding to the wavelength absorbed by the chlorophyll molecule through a plant leaf, while the leaf is still on the plant. The meter essentially measures leaf "greenness," which has been shown in numerous studies to be correlated with leaf chlorophyll content, plant N, and the likelihood of an economic response to N fertilization. The LCM allows for rapid, ongoing monitoring of plant N nutrition and is particularly well suited to irrigated crops where N can be added via the irrigation system according to LCM results. Since other nutrients affect leaf greenness, especially S, the LCM must be used with caution and with soil N testing where possible to avoid

recommending N fertilization when some other factor is responsible for the observed chlorosis (Schepers et al., 1992). Nevertheless, the LCM is an important advance in the field-scale evaluation of plant N nutrition, particularly for agronomic crops.

Remote sensing has long been recognized as a relatively inexpensive method for mapping, monitoring, and classifying vegetative cover. As discussed earlier, the high spatial and temporal variability of soil N has limited development of reliable soil tests for determination of soil N supplying capacity. However, remote sensing shows potential to overcome the shortfalls of traditional plant and soil analysis due to its ability to characterize spatial variability down to resolutions of just a few meters and to identify nutrient deficiencies in real time while applying fertilizers or other nutrient sources. Numerous vegetative indexes have been developed using knowledge of plant spectral reflectance and absorbance characteristics. For example, plants scatter or reflect the majority of near infrared (IR) radiation that they intercept due to internal cellular structures. Conversely, chlorophyll absorbs the majority of red (R) light intercepted to provide energy for photosynthesis. One such index is the normalized differential vegetation index (NDVI):

$$NDVI = \frac{IR - R}{IR + R}$$
 (13.2)

The NDVI has been widely used to assess land use, monitor crop phenology, and to estimate yields by numerous researchers. More recently, NDVI has been used to relate predicted yield to N requirements of various crops during the growing season (Shanahan et al., 2001; Chang et al., 2003). Nonetheless, remote sensing has often been of limited use in agriculture due to the cost and time associated with collection and processing of remote sensing data generated by satellites or fixed wing aircraft. However, recently portable, active optical sensors have become commercially available. These sensors emit their own light and can be hand-held or mounted on equipment, overcoming many of the shortfalls associated with satellite- and aircraft-based sensors that are reliant on reflected sunlight and vulnerable to atmospheric conditions. These sensors have been shown to reliably predict crop yields and multiple algorithms have been developed to relate various indexes to crop N requirements (Raun et al., 2005; Thomason et al., 2007). Moreover, the sensors can be used to control variable rate N application in real-time, significantly increasing N use efficiency. As sensing technologies continue to develop, they are likely to represent perhaps the most significant advance in the evaluation and adjustment of crop nutrient status.

13.3.3 Plant Analysis

13.3.3.1 Plant Analysis: Basic Principles

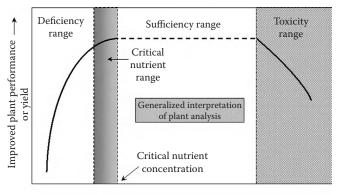

Plant analysis is defined as "...the determination of the elemental composition of plants, or a portion of the plant, for elements essential for growth. It can also include determining elements that are detrimental to growth or animals or humans through our food chain" (Munson and Nelson, 1990). The components of

a plant analysis program are similar to those used for soil testing: (1) collection of a representative sample from a plant, or the whole plant, at the proper stage of plant development; (2) proper handling of the sample to avoid contamination or damage that could affect interpretation of results, followed by accurate sample analysis using standardized laboratory methods; (3) correlation and calibration studies that establish quantitative relationships between plant analysis and plant performance; and (4) economically and environmentally sound nutrient management recommendations to correct any nutrient deficiencies. Key factors to consider in each step are described below. Many references provide detailed descriptions of the protocols used for plant sampling, handling, and laboratory analysis; hence, these topics will not be discussed (Plank, 1989; Jones and Case, 1990; Westerman, 1990; Mills and Jones, 1997).

13.3.3.2 Plant Analysis: Interpretation of Analytical Results

The two most widely used methods for interpretation of plant analysis are (1) the critical nutrient concentration or range (CNC or CNR) and (2) the diagnosis and recommendation integrated system (DRIS), which relies primarily on nutrient ratios, emphasizing the importance of nutrient balance in the plant to optimum plant performance.

Interpretation by the CNR approach relies, as with soil testing, mainly on correlation and calibration studies that show there is a statistically significant relationship between the nutrient concentration in a plant and plant response to additions of the nutrient (Figure 13.6). In most cases plant analysis results are compared to optimum CNRs, with analytical values expressed in percentages (for major nutrients) and parts per million (mg kg⁻¹ or µg g⁻¹ for micronutrients), on a dry weight basis. Nutrient concentrations below the CNR are considered deficient, those above it adequate or optimum; the CNR represents a transition zone between these two categories. The CNC is defined as the nutrient concentration where plant performance changes from suboptimum and unsatisfactory to optimum. Because the CNC is a single value that can be difficult to determine experimentally, given the uncertainties and variations associated with field studies, and because it can

Increasing concentration of element in plant tissue ———

FIGURE 13.6 Illustration of the critical nutrient range approach for plant analysis interpretation.

vary somewhat within a plant species due to genetic differences among hybrids, the CNR approach is more commonly used to interpret plant analysis results. Extensive research conducted to determine CNRs for most plants with economic value clearly show that the CNR for a plant depends upon growth stage and plant part that is sampled (Mills and Jones, 1997). Therefore, comparisons of plant analysis results with CNR values are only valid if the plant sample is taken at the same growth stage and from the same plant part used in the calibration studies conducted to determine CNRs. Interpretation of plant analysis results by this method, therefore, requires careful adherence to recommended protocols for sampling, handling, and analysis.

The balance of nutrients within a plant is often more important than the concentration of any individual nutrient. The DRIS system focuses on nutrient balance as an alternative to the CNR approach to plant analysis interpretation. One advantage of the DRIS system, compared to the CNR, is that nutrient ratios in plants tend to be more constant throughout the growing season than individual nutrient concentrations. Use of DRIS, therefore, allows for greater flexibility in the time of plant sample collection as samples do not necessarily have to be taken at a specific growth stage. The DRIS system first establishes norms for all nutrient ratios (N:P, N:K, P:K, N:S, P:S, etc.) associated with maximum crop yield. These norms can be developed from reviews of the scientific literature or by widespread sampling of a crop in a given physiographic region. As much as possible, all factors that affect crop yield are measured at the time of plant sample collection (soil test values, pest pressure, climate, cultural practices, etc.). In this way, an integrated relationship can be established between the DRIS norms, crop yield, and the other growth-limiting factors. Interpretation of plant analysis via the DRIS system can be done graphically or mathematically by the calculation of DRIS indices. The DRIS system has received intense interest and considerable research in the past decade. Computer programs that can rapidly calculate DRIS indices have been developed from this research, resulting in wider use of DRIS by plant analysis laboratories. Readers are referred to Beaufils (1973), Sumner (1979, 1981), Escano et al. (1981), Amundson and Koehler (1987), Karlen et al. (1988), Walworth et al. (1988), Munson and Nelson (1990), and Beverly (1991) for examples of the use of DRIS.

13.4 Soil Fertility Evaluation: The Future

The principles and practices used to assess soil fertility continue to evolve and it is clear that the process of soil fertility evaluation will take on new dimensions in the next decade. Given this, two important questions should be considered now. First, how should newly emerging technologies for the evaluation of soil fertility be assessed and integrated with current practices? Second, it is clear that in the past decade soil fertility evaluation has expanded well beyond production agriculture to address new challenges, especially those related to environmental protection and human health. Given this, how can we best apply the

results of "environmental" soil tests to assess the value of best management practices intended to protect or restore the environment or reduce soil-related human health risk?

13.4.1 Precision Agriculture and Remote Sensing

The past decade has seen the development of several new technologies that have the potential to significantly alter soil fertility evaluation and management. The two most important and closely related examples are "precision agriculture" and remote sensing (defined as "... the science of obtaining information about an area through analysis of data acquired by devices not in contact with the area"; Hergert, 1997). Precision agriculture, also referred to as site-specific management, has become an increasingly accepted and widespread approach to farming that allows us to (1) precisely map soil fertility in a field or on a farm at great detail (typically in 1 ha grids) through the use of hand-held or equipment-mounted GPS that use signals from a network of satellites to instantaneously locate a position on the earth's surface; (2) use variable rate application equipment, equipped with GPS and "on-the-go" sensors of soil nutrient status, to supply nutrients in accordance with these maps; and (3) generate GPS-based maps of crop yields. Factors related to yield that cannot easily be measured by soil and plant testing can be obtained from other computerized data bases (e.g., soil series from soil surveys) or be assessed using remote sensing (e.g., plant health, soil moisture, irrigation and drainage, pest pressure). The most commonly used remote sensing devices today include cameras and other imaging systems mounted on aircraft or satellites. Other, more recent examples are sensors mounted on ground equipment (e.g., tractors, pesticide applicators) or on large permanent structures (irrigation systems, electrical towers). Remote sensing devices acquire electromagnetic energy that is emitted or reflected from plants (or bare soils) and convert this energy into data that can be used in soil fertility evaluation. Each combination of soils, plants, environmental conditions, and management practices has a characteristic spectral "signature"—a specific spectrum of radiation—that can be used to diagnose soil fertility problems. As an example, IR aerial photography has been used for many years to assess plant performance because healthy green plants reflect large amounts of IR radiation while plants damaged by insects, drought, or nutrient deficiencies do not. As with traditional approaches to soil fertility evaluation, the ultimate value of these increasingly sophisticated technologies lies in our ability to interpret the results. Indeed one of the problems with precision agriculture is that vast quantities of spatially located data can be generated very quickly, creating an information overload that can confuse or obscure interpretation. Research is now underway to develop "expert systems" that use computerized GIS to integrate the various "layers" of data in a meaningful way, thus guiding a more holistic approach to crop management, of which soil fertility evaluation is only a part. Some areas in precision agriculture where research is needed include the following: (1) an economic

analysis of the value of the additional information obtained by extensive, GPS-based grid soil sampling, relative to traditional, less intensive techniques; (2) a reevaluation of current soil test calibration and correlation models given the enormous, largescale data bases that are rapidly becoming available; (3) the most effective and rapid means to obtain "ground truth"-verification of the accuracy of remote sensing devices and "on-the-go" sensors as indicators of soil fertility; and (4) the value of sitespecific management techniques for application other than crop production, such as minimizing N and P losses via leaching and runoff, irrigation scheduling, erosion control practices, and more efficient use of wastes and by-products. Readers are referred to Robert et al. (1995), Pierce and Sadler (1997), and Bongiovanni and Lowenberg-Deboer (2004), Srinivasan (2006) for reviews of precision agriculture and site-specific management and to the following Web sites from universities and private industry for examples of the latest advances in this field: (1) Australian Centre for Precision Agriculture, http://www.usyd.edu.au/agric/acpa/; (2) Cranfield University (United Kingdom) Centre for Precision Farming, http://www.cranfield.ac.uk/sas/naturalresources/ index.jsp; (3) The Ohio State University, http://precisionag.osu. edu/; (4) Purdue University Site Specific Management Center, http://www.agriculture.purdue.edu/ssmc/; and (5) Precision Ag, http://www.precisionag.com/.

13.4.2 New Directions and Uses for Soil Fertility Evaluation Techniques

The formal, institutionalized practice of soil fertility evaluation originated to serve the needs of production agriculture, a function that continues to be of unquestioned importance today. However, some of the needs of the agricultural sector are changing as, for example, in developed countries where the potential environmental impacts of soils that have become over-enriched with nutrients or contaminated by wastes and by-products from industry and urban area has begun to supersede the need to identify and correct nutrient deficiency problems. At the same time, those responsible for nonagricultural land uses are beginning to see the potential value of practices originally developed to optimize soil fertility for crop production. There are several challenges that must be overcome if the process of soil fertility evaluation is to evolve and respond to needs such as these. First is the establishment of better and more direct interfaces between nontraditional users of soil and plant testing and researchers with expertise in these areas. This will help to clarify when, where, and how it is appropriate to use current soil fertility evaluation techniques for purposes other than those for which they were originally designed. It will also provide insight into the advances in soil science research needed to more effectively address the problems faced by those charged with protecting air and water quality, preventing further damage or restoring soil quality to lands disturbed by erosion, salinization, construction, surface mining, and similar activities, and remediation of soils polluted by anthropogenic activities. Second, is the need for the public and private organizations responsible for

soil fertility evaluation to recognize the contribution they can make to solving land management problems that are not solely directed at profitable crop production. This will require better interactions with (1) researchers who have developed many new soil testing methods that have value in these areas but that have not been adopted by routine soil testing laboratories; (2) new clientele who often have unusual problems and limited understanding of the principles and practices of soil and plant testing; and (3) a wide range of technical and regulatory agencies and not-for-profit environmental groups who have the responsibility or interest in the protection and restoration of air, water, and soil quality. Strengthening these interfaces will provide the research base essential to support nontraditional uses of soil fertility evaluation techniques and the educational component needed to ensure that only the appropriate analytical methods are used and that proper interpretations of the results are made. This research should then help guide the design and implementation of best management practices that can minimize nutrient loss from land to water, stabilize (or remove) elements in soils that may be toxic to humans or other organisms, and restore ecosystems degraded by nonpoint pollution.

In conclusion soil fertility evaluation is a vital, integral part of global agriculture and plays an increasingly important role in many nonagricultural land uses, especially those related to nonpoint source pollution. Successful application of the principles and practices described in this chapter will increase the profitability and minimize the environmental impacts of nutrient use—the fundamental goal of soil fertility management. Appropriate integration of newly emerging technologies with current practices will further enhance our ability to evaluate soil fertility and make sound nutrient management decisions. Expanding the process of soil fertility evaluation to more fully include nonagricultural settings, and especially to situations where environmental protection or land restoration are the goal, is perhaps the greatest challenge we face today.

14.1 Introduction

Efficiency of nutrient application is one of the major factors affecting the overall effectiveness of a fertilizer program. There are a number of ways that the efficiency of fertilizer use can be measured, such as the percent of the applied nutrient taken up by the plant or the increase in crop yield per unit of applied nutrient. But regardless of the measure used, a number of interacting factors determine the efficiency of a given fertilizer application. The relative mobility of the nutrient of concern in the soil is foremost in importance. Nitrogen (N) is an excellent example of a nutrient that is mobile in the soil and easily lost from the root zone. Devising an application system that can provide N to the crop when it is needed is the challenge in many cropping situations. Sulfur, B, and Cl are other nutrients considered to be mobile in soils. Compared to N usage, uptake of these nutrients is rather small. However, management decisions regarding time and method of application may still be needed to ensure optimum utilization.

Phosphorus, on the other hand, is generally considered to be relatively immobile in soils. While loss of P from the root zone limiting P availability to crops may be unlikely, P is subject to a number of reactions and transformations, which can reduce P availability to the plant. Placement techniques that minimize the effects of these transformations and enhance P availability are potentially valuable to crop managers.

In choosing appropriate application technology, a number of characteristics of the system beyond nutrient mobility must also be considered. These include the nature of the crop being fertilized, weather and climate, soil properties, the form in which the nutrient is applied, the method of application utilized, and the timing of the fertilizer application in relation to nutrient needs of the crop. By understanding how these individual factors interact, one can devise an efficient system of nutrient delivery requiring the least possible amounts of fertilizer, yet achieving optimum growth and subsequent yield.

To arrive at useful and effective decisions with respect to fertilizer application, it is necessary to have some understanding of how plant nutrients get to the root system. There is general agreement that nutrients reach a root by three primary mechanisms: mass flow, diffusion, and root interception.

Mass flow is somewhat self-descriptive. Nutrients dissolved in the soil solution/water move to the surface of the root as water is taken up by the plant. Mobile nutrients such as N, S, B, and Cl, and immobile nutrients present in high concentrations in the soil solution such as Ca and Mg move to the root surface with soil water through mass flow. Diffusion is a process whereby soil nutrients move from an area of high concentration to an area of lower concentration near the root surface created through nutrient uptake. Immobile nutrients such as P, K, and the micronutrient metals move to the surface of the root by diffusion. Diffusion takes place over relatively short distances (<1 mm). Fertilizer application methods, which create zones/areas of high nutrient concentration such as fertilizer banding, can facilitate diffusion. However, only the portions of the root system in, or in direct contact with the high nutrient availability zones are impacted.

Root interception is simply the process where the root intercepts plant nutrients as it grows through the soil. Both mobile and immobile nutrients are made accessible for nutrient uptake by this process.

14.2 Application of Mobile Nutrients

Of the 14 mineral nutrients considered essential for plant growth, N, S, B, and Cl are generally considered to be mobile in soils. Because of the differences in magnitude of uptake and sources available for use in a fertilizer program, the application of each will be discussed separately.

14.2.1 Nitrogen

Application of N is a major concern in the production of most nonlegume crops. When developing an N fertilization program today, the modern grower is faced with decisions about (1) the rate of N to apply, (2) fertilizer source or sources to use, (3) when to apply N to ensure adequate amounts present at key crop growth stages, (4) method of application, and (5) the use of compounds such as nitrification or urease inhibitors, or specialty fertilizer products such as coated urea to prevent N loss.

14.2.1.1 Nitrogen Sources

There are numerous sources of N that have been used for crop production over the years. The three N sources most commonly used for field crop production in the United States today are anhydrous ammonia (82-0-0), urea-ammonium nitrate solutions (28-, 30- or 32-0-0), and granular urea (46-0-0). In addition, significant amount of ammonium nitrate (33-0-0) and ammonium sulfate (21-0-0-24S) are also applied in some areas. Nitrogen is also added as a secondary component in many multiple nutrient fertilizers. These include the dry granular ammonium phosphates diammonium phosphate, DAP (18-46-0), monoammonium phosphate, MAP (11-52-0), and liquid ammonium polyphosphates (10-34-0 and 11-37-0). Many by-product N sources are also marketed as fertilizers, such as dry or liquid ammonium chloride. The choice of the source of fertilizer N is dependent on a number of factors such as the local availability of a specific product, cost of the product per unit of N, safety issues related to using the product, application equipment available and cost of application, time required and availability of custom application, N loss potential of the soils in that particular field, cropping system and residue cover, rooting patterns of the intended crop, and other individual factors.

The relative advantages of one fertilizer N source over another has been widely debated and consequently studied at length. In most studies with field crops, when care was taken to prevent N loss, most N sources have an equal effect on yield when used at rates that supply the same amount of N. Where differences have been observed, the differences can generally be explained by some factor that makes a particular source susceptible to N loss in that particular application. Examples would include (1) a surface application of urea in a high pH or high residue situation

leading to N loss from ammonia volatilization; (2) the broadcast surface application of urea ammonium nitrate (UAN) solutions to a soil covered with large amounts of a wide C:N residue such as wheat straw or corn stalks resulting in N immobilization; (3) preplant applications of granular ammonium nitrate for corn on a sandy soil prone to leaching loss; (4) or an early fall preplant application of anhydrous ammonia for corn on a poorly drained soil prone to denitrification in a humid climate.

In each of these examples, N loss could have been reduced and the source successfully used through incorporation of the fertilizer or the addition of a urease inhibitor with the urea in example 1; placement of the UAN below the wide C:N residue through subsurface banding in example 2; use of a high N starter fertilizer followed by sidedressing with the ammonium nitrate in example 3; and delaying the application of the fall preplant ammonia to spring, and/or adding a nitrification inhibitor such as nitrapyrin to reduce denitrification in example 4. As these examples show, N source selection when developing an N management plan is not a decision that can be made independently of many other factors such as N loss potential from leaching, denitrification, immobilization and ammonia volatilization, application equipment available and time available for application, safety, and cost.

14.2.1.2 Time of N Application

The optimum time for N applications to agronomic crops generally revolves around three key factors, (1) the intended crop, architecture of the root system, nutrient uptake pattern, and when physiologically it demands N for key stages in crop growth, (2) the potential for N loss at that particular site, as a function of both climate and soils, and (3) time available for nutrient application in the cropping system. Using time of application as a management tool to avoid loss of N fertilizer will be discussed in detail in the following section.

Growth and development of the crop, and especially of the root system, are important factors to consider in timing decisions. Because of the downward mobility of NO₃-N in soils, more frequent applications of fertilizer N have been most effective for shallow rooted crops such as edible beans and potatoes, especially on sandy soils. Nitrogen uptake by crops is also not constant throughout the growing season. For crops such as wheat, barley, oats, and corn, for example, the rate of N uptake is slow during the early part of the growing season, accelerates before anthesis, and stops or decreases rapidly after pollination. Therefore, N fertilizer should be supplied in such a way as to meet the minimal needs of the young seedling, while providing the majority of the N throughout the later stages of vegetative growth, but be completed before grain fill is started. In the case of corn on sandy soils, where NO₃-N can move quickly below the root zone, a preplant or starter application to support early growth followed by a sidedress application at the four to eight leaf stage is generally adequate on nonirrigated sites. Under high-yielding irrigated environments, additional N applications prior to tasseling can be beneficial, both to ensure adequate N for grain fill, and to reduce the movement of NO3-N below the root zone facilitated by the application of irrigation water.

With winter wheat, an application of N at seeding, either through broadcasting N or applying N with the planting equipment to enhance fall growth and tillering, followed by a top-dress application applied between green-up and "jointing," or initiation of stem elongation, is common. In the high-yielding, intensive management systems used in the Mid-Atlantic and Ohio River Valley regions of the United States, multiple topdress applications are commonly made. In regions where winter wheat is a dual purpose crop used for both forage production and grain, higher rates of N applied prior to or at planting to stimulate fall and winter vegetative growth, followed by a heavy topdressing in early spring to stimulate grain production is common.

On well-drained medium to fine textured soils, timing of the applications of fertilizer N is more flexible for deep rooted crops such as corn and wheat in many environments. In many of these situations, time of application has little effect on yield, as long as adequate N is present to meet the needs of the crop at key physiological growth stages such as ear or head initiation/development. Nitrogen loss and environmental concerns may also be minimal in many environments. In these situations, applying N in a single application prior to planting can be a reasonable system to use for many crops.

Timing of needed fertilizer N is also an important consideration in the production of forage grasses. Because cool season species such as tall fescue and smooth brome grass produce most of their dry matter in late spring and early summer, fertilizer N should be applied before this season of rapid growth. How the forage is utilized, whether harvested for hay or used for grazing, and whether the N is applied alone or in combination with other nutrients can also influence the time of N application. When using cool season grasses for hay, making a single application of N in the early spring before or at green-up is common. When making a combined application of N with P, a late fall application to stimulate tillering and root growth is preferable in many environments. In environments where cool season grasses are used for grazing, especially fall grazing, or a second cutting of hay is made, splitting the N application with the majority of the N and any needed P applied in the fall or early spring followed by an application of the balance of the N in mid- to late summer to stimulate fall growth, can be beneficial.

In contrast, the majority of the growth of warm season species occurs when temperatures are high and therefore application of fertilizer N should be delayed until after the initiation of the warm season grass growth to minimize stimulation of cool season invasive grass and weed species. In the case of high-yielding, intensively managed species such as Bermuda grass, multiple applications of N are generally more efficient than single, early season N applications.

14.2.1.3 Managing Fertilizer N to Prevent Losses

Nitrogen is lost from agricultural soils primarily by (1) leaching, (2) denitrification, and (3) ammonia volatilization. In addition, N can be transformed to unavailable forms through immobilization and ammonium fixation. Detailed reviews of each of these processes can be found in Section 27.1 of *Handbook of Soil Sciences: Properties and Processes*, Hauck (1984), Scharf and

Alley (1988), and Schepers and Raun (2008). However, some basic fundamental concepts will be discussed to facilitate the understanding of how application techniques may minimize the impact of these processes.

Leaching is simply the downward transport of NO₃- (and NH₄⁺ in low cation exchange capacity [CEC] soils) with water. Leaching occurs when water reaching the soil surface from precipitation and/or irrigation exceeds evaportranspiration (Nelson and Uhland, 1955). Leaching is a special concern in the more humid climate of the eastern United States, where precipitation exceeds evapotranspiration by 150-500 mm annually, or where irrigation is used. Soil water-holding capacity also plays an important role in determining the importance of leaching losses. Soil with a high water-holding capacity, such as silt loams, can accumulate large quantities of water before NO₃⁻ is transported below the root zone. Thus, soils with high water-holding capacities are much less prone to leaching losses than coarse textured, low water-holding capacity soils. Tile drainage, such as is commonly used in the midwest, can enhance leaching by providing a shallow outlet for drainage to surface water sources.

Denitrification is a microbial process by which soil bacteria (facultative anaerobes) utilize the O in $\mathrm{NO_3}^-$ and $\mathrm{NO_x}$ and $\mathrm{N_2}$ gases are released into the soil atmosphere and are subsequently lost. A number of factors or conditions interact to impact the rate of denitrification. These include energy sources such as soil organic matter (SOM), crop residue, and animal manure, moisture/ $\mathrm{O_2}$ availability, temperature, and pH (Wijler and Delwhiche, 1954; Bailey and Beauchamp, 1973; Burford and Bremner, 1975; Rolston et al., 1978). Denitrification is the primary N loss process and is a major concern for finer textured poorly drained soils, or soils with high seasonal water tables.

Ammonia volatilization is the gaseous loss of free NH3 to the atmosphere from soil and fertilizers. There are three general situations where NH₃ volatilization is a significant loss problem. When NH4+-based fertilizers such as ammonium sulfate are broadcast on the surface of high pH or alkaline soils and not incorporated, some NH₄ is converted to NH₃, which can volatilize to the atmosphere. This only occurs in significant amounts with pH > 7. When urea-based fertilizers are applied to soils, the naturally present urease enzyme hydrolyzes the urea to NH₃. The hydrolysis reaction generates enough OH- ions to temporarily raise the pH of the soil around the urea fertilizer, which, in turn, causes NH3 volatilization. Volatilization of N from urea is enhanced if urea is applied to a soil surface covered with crop residue or vegetation, as in a no-till corn field or a pasture or hayfield. Ammonia volatilization in cases one (volatalization from ammonium sulfate at high pH) and two (volatalization from urea) is exacerbated by the evaporation of water from the soil surface. The third situation deals with the addition of urea- or NH4-based fertilizers to flooded rice paddies. A diurnal fluctuation in pH due to algal utilization of CO₂ results in a rapid rise in water pH reaching a maximum of 7–10 during midday. The high pH favors the conversion of NH4 to NH3, and its volatilization. In all cases, incorporation of urea- or NH4-based fertilizers into the soil effectively stops volatilization (Ernst and Massey, 1960). Unfortunately, incorporation is not always possible so alternative management strategies are sometimes utilized.

There are a number of alternative application strategies that can be used to reduce leaching loss of N from agricultural soils. Probably the most commonly used is timing of fertilizer applications to match periods of rapid utilization by crops. The use of sidedressing, delaying applications of N fertilizers until the crop is established and taking up N, or the use of split applications to avoid N leaching losses is common for crops such as corn, wheat, and cotton, particularly on sandy soils. An example of how time of N application has been used to enhance N use efficiency on coarse textured soils by reducing leaching losses can be found in Evanylo (1991).

The use of nitrification inhibitors and slow-release fertilizers is an alternative strategy to application timing as a means of reducing N loss from leaching. While the use of nitrification inhibitors has proven to be a successful means of reducing N loss on fine textured soils in the Eastern Corn Belt (Huber et al., 1982; Stehouwer and Johnson, 1990; Mann, 1995), they have shown mixed results in irrigated areas and the western Corn Belt (Maddux et al., 1985; Cerrato and Blackmer, 1990). A number of slow-release fertilizer products have been studied and have potential for reducing N loss from leaching in coarse textured soils.

Many of the same strategies that are used to avoid leaching losses can be used to avoid losses from denitrification, namely, timing of application, the use of slow-release fertilizers, and nitrifications inhibitors. However, one important difference among soils where these problems occur must be emphasized. Soils prone to high rates of leaching loss tend to be well drained, with low water-holding capacity. These soils dry rapidly after a leaching event and a farmer has a high probability of being able to drive across these fields in a short period of time. Many of these fields may be irrigated, which allows for the application of fertilizer N with irrigation water (fertigation). Soils prone to high rates of N loss through denitrification are not usually irrigated and tend to be poorly drained and slow to dry and trafficability is reduced. Thus, while sidedressing or split N applications are excellent tools to reduce N loss from denitrification, they entail risk to the grower who chooses to use them on poorly drained soils. This is a risk that additional N may not be applied in a

Nitrification inhibitors are useful tools for reducing N loss in soils prone to denitrification. A number of studies in fine textured soils of the eastern Corn Belt have shown responses to the use of nitrification inhibitors with fall or spring preplant applied N (Frye et al., 1981; Huber et al., 1982; Stehouwer and Johnson, 1990).

Incorporation of the urea-N into the soil is the most effective strategy for reducing N loss from $\mathrm{NH_3}$ volatilization (Ernst and Massey, 1960). While this is not always possible with no tillage systems, a number of tools have been developed to allow injection or banding of N fertilizers in these production systems. A number of studies have demonstrated that injection of N fertilizers into the soil and below the surface residue in corn and grain

sorghum greatly enhances N use efficiency (Mengel et al., 1982; Lamond et al., 1991). Irrigation water can also be used to incorporate urea into the soil to reduce NH₃ volatilization (Mengel and Wilson, 1988).

Choosing a nonvolatile N fertilizer source is another alternative (Bandel et al., 1980; Fox and Hoffman, 1981). Ammonia volatilization losses from ammonium nitrate and ammonium sulfate are negligible compared to those from urea or urea-based products (Keller and Mengel, 1986).

Urease inhibitors are another management tool available to reduce NH₃ production until after the urea has been incorporated into the soil by rain or irrigation water. At present, one urease inhibitor, N-(n-buty1) thiophosphoric triamide (NBPT) is commercially available in the United States. Research has shown that urea impregnated with NBPT is a viable alternative to a nonvolatile N source such as ammonium nitrate. Coated urea products, such as polyurethane coated urea are also useful in reducing NH₃ volatilization.

14.2.2 Sulfur

Sulfur, like N is mobile in soils, yet its transformations and chemistry differ considerably from many of the reactions associated with N. Because S is mobile, many of the best management practices suggested for use of fertilizer N are also appropriate for the management of fertilizer S. Compared to N, S is utilized in relatively small amounts by actively growing crops. Various research projects have evaluated the effect of rate and management of S fertilizers on production and quality of a variety of crops. Specific management practices associated with optimum production vary with the crops that are grown.

The legumes, (alfalfa, clovers, soybeans) and canola remove relatively large amounts of S from the soil system while other crops (corn, small grains, forage grasses) remove smaller amounts. Options for placement of fertilizer S also vary with the intended crop.

Approximately 90% of the total S in soils is found in SOM, which can supply substantial amounts of S for crop production. Traditionally, research has shown that crops grown on fine textured soils with a high SOM do not respond to the application of fertilizer S. On the other hand the use of fertilizer S has produced dramatic increases in yield when applied to crops grown on sandy soils with a low SOM content (Section 11.4). Recent reductions in the atmospheric deposition of S may be altering this relationship however. Reports of S fertilizer responses appear becoming more widespread in recent years.

14.2.2.1 Sulfur Sources and Methods of Application

Application of S in a fertilizer program is most frequently associated with the production of alfalfa and other perennial legumes, corn, and small grains. As reported by Hoeft and Walsh (1975), alfalfa responds favorably to annual topdress applications of fertilizer S. Products containing elemental S (>90% S) or SO_4 form can be used for this method of application. The most common dry sources of SO_4 -S are ammonium sulfate (24% S) and the

double salt of potassium and magnesium sulfate (22% S). If K is needed in a fertilizer program for alfalfa, the double salt is a logical choice for topdress applications. Cogranulated ammonium phosphate products containing both elemental and SO₄ forms of S are also available and would be logical products to use if P were needed. Perennial grasses have also responded to annual topdress applications in situations where S is needed in a fertilizer program (Lamond et al., 1995). In general, annual applications of fertilizer S are suggested for all perennial crops whenever there is a need for S in the fertilizer program. Although legumes such as alfalfa generally remove substantial amounts of S from soils, soybeans have not responded consistently to S fertilization. Yield increases have been noted when fertilizer S is applied on very sandy soils (Matheny and Hunt, 1981) but not on fine textured soils (Brown et al., 1981; Sweeney and Grande, 1993). Sulfur needed for soybeans can be either broadcast before planting or applied in a band at planting. There is no research information to suggest that one method of application is superior.

When corn is grown on sandy soils where responses to S fertilization might be expected, the needed S can either be broadcast and incorporated before planting or applied as a starter fertilizer at planting (Hoeft et al., 1985; Kline et al., 1989). In general, rates of applied S are doubled if S fertilizer is broadcast and incorporated before planting rather than applied in a band near the seed at planting. There is general agreement that the use of split applications of N fertilizers is a best management practice for corn production on irrigated sandy soils. In evaluating the timing of S applications for sandy soils, however, a single application at planting has been as effective as split applications during the first half of the growing season (Rehm, 1993). When wheat and other small grains are considered, responses to S fertilization are not frequently reported. The majority of responses reported have been for the silt loam soils of the Pacific Northwest where broadcast applications have been popular (Ramig et al., 1975; Mahler and Maples, 1987). Responses have also been observed in wheat recently in the sandy, low SOM soils of the central and southern Great Plains.

When fluid fertilizers are used for production of annual crops, S can be supplied as ammonium thiosulfate (26% S) or potassium thiosulfate (17% S). Although these fluid materials are best suited for a band application at planting, caution should be used because germination can be impaired if ammonium thiosulfate is placed in contact with the seed. The safety of potassium thiosulfate when placed in contact with the seed has not been fully documented. Fluid fertilizer containing S can also be injected into irrigation water. This is not a preferred practice and should be limited to correcting identified S deficiencies.

14.2.2.2 Managing Sulfur to Prevent Losses

When present as SO_4 -S, downward movement through soils can occur during either heavy rainfall or over-irrigation. The rate of downward movement of SO_4 -S is, however, not as rapid as that of NO_3 -N. Unless excessive amounts of irrigation water are applied to sandy soils, leaching of SO_4 -S should be of minor concern. Because SO_4 -S is not associated with problems of water quality,

its loss by leaching is of economic concern, which can be minimized by applying fertilizer S, when needed, in a band close to the seed at planting.

14.2.3 Boron

This essential nutrient is also mobile in soils. Boron, which is found in soils as uncharged H₃BO₃, is not strongly sorbed by soil particles and is susceptible to leaching. Boron is classified as a micronutrient because small amounts are required for optimum crop production. The majority of the research conducted with B fertilization on agronomic crops has focused on the production of alfalfa (Brown, 1972), corn (Touchton and Boswell, 1975), small grains (Gupta et al., 1976), cotton, and peanut. Positive responses have not been consistent and are limited to unique soils and/or situations. As with N and S, annual applications of B are suggested often as broadcast preplant applications with annual crops or topdress applications or foliar applications on perennials, such as alfalfa.

Since B applied with the seed can cause germination problems and seedling injuries, especially for oilseeds, broadcast applications incorporated before planting are suggested for all annual crops and placement of B in contact with the seed should be avoided. Foliar application of B is routine for many crops, including cotton (Roberts et al., 2000) and peanut (Gascho and Davis, 1995).

14.2.4 Chloride

Chloride, like B, is mobile in soils behaving like NO₃-N in terms of leaching (Endelman et al., 1974). Although not studied intensively, responses to this nutrient have been documented for corn (Heckman, 1995), sorghum (Mengel et al., 2009), and small grain production in limited situations, and especially where applications of potassium chloride are not routinely made (Fixen et al., 1986a, 1986b; Engel et al., 1994). Because Cl⁻ is mobile, placement should have little effect on crop response to this nutrient. In contrast to the management of N, there is no indication that split applications would be superior to a single application at or before planting. Common sources for Cl⁻ include many soluble salts such as KCl, CaCl₂, MgCl₂, and NaCl, and NH₄Cl.

14.3 Application of Immobile Nutrients

Nutrients such as P, K, Ca, Mg, Zn, Cu, Fe, and Mn that are strongly sorbed by soil components are immobile and do not move easily through soils (Chapter 11). Unless there are substantial losses of soil from the landscape, there are usually no significant losses of immobile nutrients from the soil system other than through crop removal. There are situations however, where nutrients normally considered immobile can move through a soil profile. Two examples are leaching of K⁺ and Mg²⁺ in soils with a low CEC and leaching of Mn²⁺ and Fe²⁺ through very sandy soils that are poorly drained.

Placement consideration: Fertilizer placement becomes a major management consideration in the overall management of immobile nutrients with the following options available.

14.3.1 Broadcasting

Broadcasting with or without soil incorporation is the most commonly used method of application for immobile nutrients. Throughout the United States, a very high percentage of P and K fertilizers are applied in this manner. With this placement option, especially when coupled with incorporation through tillage, essentially 100% of the top few cm of topsoil comes in contact with the applied fertilizer. Some of the advantages of broadcast applications are as follows: (1) it is fast and easy; (2) there are several opportunities for application that can reduce the workload at critical times during the year; (3) there is high probability that crop roots will come in contact with fertilized soil especially when incorporated with some form of tillage; and (4) when soils have low CEC, there are more potential sites for adsorption and subsequent retention of K and Mg. Some of the disadvantages of this placement option are as follows: (1) thorough mixing with tillage increases the probability of fixation and reduced availability; and (2) it is difficult to achieve a uniform application of low rates of fertilizers that supply the immobile nutrients.

14.3.2 Banding

Banding fertilizer is a mechanical technique in which some device is used to open a furrow or trench and the fertilizer is applied in a band below the soil surface. With most band applications, <1% of the top soil (15 cm) volume comes in contact with the fertilizers. The common band placement options include (1) placing a low rate of fertilizer in close proximity to the seed to enhance availability of nutrients to young plants (starter); (2) placing a low rate fertilizer in direct contact with the seed at planting (pop-up); and (3) concentrating fertilizer in the root zone to overcome fixation reactions and create zones of high fertility.

In North Carolina, Nelson et al. (1959) compared various band placement options to broadcast applications of P for corn and cotton production. Using low rates of P on P-responsive sites, they found that band placement enhanced early growth and resulted in better utilization of the applied P. There were, however, no differences in yield. Barber (1958) established a long-term study in Indiana and evaluated both the direct and residual responses to broadcast and band placement of P fertilizers. He found that band applications provided the greatest response when the P soil test was low, and that the advantage decreased as the soil test for P increased. This study also showed that the production of optimum corn yields required both broadcast and banded application of P fertilizer at low soil test P levels. Welch et al. (1966a, 1966b) found similar results with the application of both P and K in Illinois. With low fertilizer rates on responsive soils, band application resulted in more efficient utilization of immobile nutrients. However, highest yields were obtained by combining both band and broadcast application at higher rates. For soils with higher soil test values, response to fertilizer was smaller and placement had only limited effects on use efficiency and yield.

The primary advantages of banded application of immobile nutrients are as follows: (1) it creates a zone(s) of enhanced nutrient availability by minimizing contact between soil and fertilizer and (2) it is a simple and efficient method of applying small amounts of fertilizer. Disadvantages include (1) only a limited portion of the root system has high probability of coming in contact with the fertilizer; (2) damage to germination can occur when high rates of some fertilizer products are placed too close to the seed; and (3) the cost of equipment used in banding can be high.

With the continued expansion of no-till production systems, and introduction of strip-till systems, the use of deep banding to place fertilizer 15-20 cm deep below the row area has gained considerable interest. This practice avoids the concentration of nutrients near the soil surface, vertical nutrient stratification, which commonly occurs with broadcast applications when not accompanied with incorporation. In most deep banded situations, a tine or shank device is pulled through the soil doing some tillage with the fertilizer released at some depth below the surface. The depth of placement used varies from 10 to 30 cm. The volume of soil mixed with the fertilizer varies widely, but is still limited in most cases. In most cases, the crop is then planted into the tilled strip, directly over the fertilizer band. Work to date has shown only limited response to deep banding of P and K as compared to traditional starter fertilizer application or broadcasting similar rates of fertilizer in corn, soybean, and wheat production in the United States (Bordoli and Mallarino, 1998; Rehm and Lamb, 2004; Martin, 2009).

14.3.3 Strip Application

In strip application, a compromise alternative to band and broadcast applications, the fertilizer supplying the immobile nutrients is placed in a band on the soil surface that is then incorporated with some tillage. By varying the width of the surface band and the type of tillage used for incorporation, 5%-15% of the volume of the surface soil is mixed with the fertilizer. While the level of nutrient availability in the treated zone may be lower than with other banding options, a much larger portion of the root system can potentially come in contact with the fertilizer. This has enhanced uptake of immobile nutrients. Nelson et al. (1959) were the first to test this concept with corn and cotton and found that a combination of in-row or seed-placed phosphate with stripping resulted in the best utilization of P by young seedlings. In a 5 year study with P and K, Barber (1974) found that strip application produced significantly higher corn yields when compared to either banding or broadcasting equivalent rates.

14.3.4 Point Fertilization

In its simplest form, this consists of opening a hole in the soil with a stick or hoe, and placing a quantity of fertilizer into the soil near the crop to be fertilized. An early study conducted by

Coe (1926) in Iowa compared broadcast application to hill placement, or short bands of fertilizer 7.5–15 cm long and 3–4 cm wide at the same depth as the seed. He concluded that banding the fertilizer in the hills was equal or superior to broadcasting, if contact between fertilizer and seed was avoided, and suggested that the fertilizer should be placed to the side of and below the seed. When used at moderate rates, fertilizer could be placed in the hill with the seed, but at high rates, the fertilizer should be split with part applied in the hill and part broadcast.

The point system is commonly used today in the production of perennial shrub or tree crops. Holes are dug near the outer edge of the canopy (drip line) of trees and fertilizer placed in those holes. Tree stakes, solid blocks of fertilizer shaped to facilitate pushing them into the ground, can also be placed at points along the outer edge of the canopy. In many developing countries, a whole is dug near or in a hill of corn or sorghum and a small quantity of fertilizer is added to maximize nutrient utilization and to minimize competition from weeds. Large individual granules of fertilizer (super granules) have been developed specifically for this purpose. With a point application system, only a very small portion of the soil, generally much <1%, will come in contact with the fertilizer.

14.3.5 Application with Irrigation Water

Fluid fertilizer can be injected into irrigation water but in the case of immobile nutrients, particularly P, this method of application has limited use. Research evaluating this placement has been reviewed by Mikkelsen (1989).

14.3.6 Foliar Application

Although the majority of nutrients needed for growth and development of plants enter through the root system, beneficial effects of foliar fertilization have been reported. For example, Shafer and Reed (1986) studied the foliar absorption of 31 organic and inorganic compounds. Much of the research effort on foliar fertilization has been summarized by Alexander and Schroeder (1987).

14.4 Placement of P and K Fertilizers

The efficiency of use of the immobile nutrients has been the focus of field and greenhouse research projects for many years. In most cases, these studies have focused on the relative advantages or disadvantages of banding versus broadcasting of P and K fertilizers. The impact of the placement of immobile nutrients on uptake by crops and subsequent yield has been studied in both the laboratory and the field. Mechanistic models to explain some of the complex relationships that influence crop response to fertilizer placement were developed by Claassen and Barber (1976), Anghinoni and Barber (1980), and Barber and Cushman (1981).

Using 33 diverse soils to test the Barber-Cushman model, Kovar and Barber (1987, 1988, 1989) found that the concentration

of P in the soil solution was the soil parameter that had the greatest effect on P uptake. When P fertilizer was placed in contact with small volumes of soil, banding produced the largest increase in soil solution P for each unit of applied fertilizer. However, the number of roots that can come in contact with the increased solution P is limited by banding. Since roots have a finite capacity to take up nutrients, it is possible that although banding increases the concentration of P in the fertilized zone, restricted root volume in contact with the high P zone could limit uptake. Using the Barber-Cushman model to predict the optimum volume of soil that should be fertilized, they found that the optimum volume varied substantially from a low of about 3% to a maximum of 15%-20%. Borkert and Barber (1985) found a very close relationship between predicted and measured P uptake by soybeans as a function of soil volume fertilized in a pot experiment. Barber (1995) concludes "Placement of P is most important in soils low in available P that sorb or fix large quantities of added P." Phosphorus placement also becomes more important as the rate of applied P decreases.

Although the quantity of P taken up by crops is only a fraction of that of K, fertilizer placement effects are similar for both. The use efficiency of banded K for corn is greater at low soil tests value for K with the difference between banded and broadcast diminishing as soil test K increases (Welch et al. 1966a, 1966b).

14.4.1 Field Comparison of Placement Options

Field comparisons between band and broadcast applications of P and K fertilizers show that banding, especially for P fertilizers, produced greater yield increases when equal rates were used for both. The results summarized by Welch et al. (1966a, 1966b) are typical of many of the results reported.

Working with several forage crops, Sheard (1980) concluded that the banded application of 30 kg P ha⁻¹ increased seedling growth as much as fivefold regardless of the species and soil test for P. Working with oats grown on contrasting soils in a greenhouse, Sleight et al. (1984) concluded that the beneficial effects of banding are obtained mainly from placing all the immobile nutrients where contact by active roots is likely, rather than from an increase in availability that may be obtained from the decreased soil/fertilizer contact associated with banding.

Some research utilizing a wide range of application rates has shown that rate can influence the effect of placement. Barber (1958, 1959) has shown that at high fertilization rates, broadcast applications may give higher yields than band applications while Welch et al. (1966a, 1966b) have demonstrated that the optimum combination of banding and broadcasting can be a complex interaction of application rate and soil test level.

With P and K fertilizers, the most frequent placement is to the side of and below the seed at planting (starter fertilizer). In the midwest United States, starter fertilizer has consistently affected early season growth more than yield (Randall and Hoeft, 1988). Starter fertilizer application has consistently been more beneficial in no-till than conventional or clean till corn (Reeves and Touchton, 1986; Mengel, 1992). This benefit, in part, may be

attributed to the fact that in no-till the soil is generally cooler in the spring and has a higher bulk density and thus early root growth is inhibited. Starter fertilizer effects are generally found to be greatest when soil temperatures are lowest (Kitcheson, 1968).

Earlier planting dates typically coincide with cooler soil temperature resulting, in slower root growth and metabolism. Although crops typically respond to starter fertilizer under these planting conditions, starter can also increase growth and grain yield on late planted corn, when soil temperatures were very warm (Farber and Fixen, 1986). This was also found to be true on Coastal Plain soils where inherent soil strength inhibits root growth and exploration (Karlen et al., 1984).

Much debate has focused on which nutrients in a starter fertilizer are responsible for the increased early season growth and subsequent increased grain yield, particularly under no-till. In Wisconsin, Motavalli et al. (1993) obtained a response to starters containing N and P in only 1 of the 3 years where manure had been applied. In Illinois, under conventional tillage on a soil with high residual P, an N and P starter fertilizer increased early season growth without increasing final plant dry weight or yield (Bullock et al., 1993). In Indiana, N was the most important nutrient in the starter solution on soils containing adequate levels of P and K (Mengel, 1992). In Alabama, Karim and Touchton (1983) found N primarily responsible for increased growth 14 days after emergence, but P appeared to have the greatest effect at 28-42 days. Wright (1985) found improved yields and earlier maturity in Florida when using a starter fertilizer containing N and P on a high P soil.

Occasionally, fertilizer will be broadcast at planting specifically to enhance early growth. With no-till corn at several locations, Mann (1995) showed that broadcast applications of 44 kg N ha⁻¹ as urea-ammonium nitrate solution negated the response to N containing starter fertilizer in no-till corn. This broadcast application of fluid N, many times used as a carrier for burndown herbicides, has become a common practice in some areas of the midwest United States where large corn planters do not routinely have starter fertilizer attachments.

While N and P are the two nutrients most commonly used in starter fertilizers, a number of others are routinely applied including K, S, Mg, and Zn. Starter fertilizer bands provide a convenient delivery system for micronutrients in many crops. For example, Miner et al. (1986) obtained a response to Mn applied in a starter on an Atlantic Coastal Plain soil that was Mn deficient due to excessive liming. The low dissolution pH of common starter fertilizer materials such as MAP can enhance the availability of micronutrient metals such as Zn, Mn, Cu, and Fe. The addition of S compounds in starter fertilizer bands can further lower pH and provide an even greater increase in metal solubility.

In general, the band application of immobile nutrients has proven to be a cost effective method of fertilizer placement, particularly when soil tests values are in the low or very low range. Either band or broadcast applications have been effective when P or K soil test values are in the medium or high range.

A combination of broadcast and band applications seem to be most valuable at lower soil test values.

The effect of placement of immobile nutrients has also been evaluated for small grain production. As with corn, band applications have been superior to broadcasting, particularly at lower rates of fertilizer (Sander et al., 1990). The distance between bands is not a concern when immobile nutrients are applied with a drill but could pose a problem when phosphate is applied in a subsurface band before planting small grains. Comparing spacing of 25, 30, and 50 cm, Maxwell et al. (1984) reported that spacing affected P uptake by young plants but had no effect on grain yield.

The residual effects of both broadcast and banded applications of phosphate are also important for small grain production. Following the harvest of spring wheat, Selles (1993) measured greater availability of P in soil samples collected directly over the band. When P was banded in soil having a range of soil test levels established by previous broadcast applications, Alessi and Power (1980) reported that the effects of the combination of band and residual effects of previous broadcast applications are additive.

Starter fertilizer usually involves the application of a small amount of fertilizer close to the seed at planting for the purpose of enhancing the early season growth of crops. In some cases, the starter fertilizer is placed directly in the seed furrow. This pop-up or in-furrow placement should only be used with crops, such as corn and small grains, which are relatively salt tolerant. There are a number of reports of injury to corn seedlings from fertilizer placed in direct contact with the seed (Coe, 1926; Allred and Ohlrogge, 1963; Creamer and Fox, 1980), sometimes resulting in stand reductions (Mengel, 1992; Gordon and Whitney, 2001). The amount of fertilizer that can be placed safely on or in contact with seed varies with crop, row spacing, soil moisture, properties of the fertilizer, and climate. For corn in Indiana, a maximum fertilizer rate of 5.6 kg N plus K ha-1 on silt loam or heavier soils is recommended for seed placement (Mengel, 1992). Similar recommendations can be found from many Land Grant Universities. The use of seed-placed fertilizer is a common practice for small grain production and no damage has been reported unless excessive, uneconomical fertilizer rates are used. An exception is urea containing fertilizers. Urea is particularly harmful to seed, due to the formation of free ammonia upon hydrolysis and it is not recommended for placement with the seed. Soybeans are much more sensitive to seed placed, popup fertilizer and this practice has severely reduced germination and subsequent yield (Clapp and Small, 1970; Hoeft et al., 1975). Consequently, seed placement of fertilizer is not recommended, regardless of rate, with soybeans.

14.4.2 Fertilizer Placement in Conservation Tillage Systems

The principles for placement of P and K fertilizers (Section 14.4.1) were developed primarily in production systems using a moldboard plow for primary tillage. Because of the emphasis on soil conservation, tillage systems are changing to minimize soil

disturbance resulting in less incorporation of broadcast P and K fertilizers with a subsequent reduction in the redistribution of nutrients in crop residues (Larson, 1964).

The stratification of immobile nutrients in the conservation tillage production systems has been documented for a variety of soils (Cruz, 1982; Weil et al., 1988; Robbins and Voss, 1991; Rehm et al., 1995; Hollanda et al., 1998). In no-till or reduced till systems, extremely high levels of immobile nutrients can accumulate in the top 4 or 5 cm of soil because of lack of incorporation of fertilizers and nutrient cycling through the nutrient containing residues remaining on the soil surface. Interestingly, this stratification is not restricted to no-till and ridge-till but is also found with chisel plowing and shallow tillage systems (Cruz, 1982; Hollanda et al., 1998).

In addition to vertical stratification, horizontal stratification can also occur. Work in Indiana clearly shows that the nutrients can accumulate near the old row area when the crop row is consistently placed in the same area, a controlled traffic system. Thus, nutrient stratification can occur in both vertical and horizontal planes. Unless a substantial portion of the root system develops near the soil surface, in the zone of nutrient enrichment, and the root environment is conducive to nutrient uptake, stratification can reduce the amount of nutrients available for uptake by the actively growing crop. A number of studies have shown that roots do concentrate in fertilized zones of soil, particularly in areas of high P (Barber, 1995) and this can be near the soil surface, especially in more humid climates (Cruz, 1982; Kaspar et al., 1991; Hollanda et al., 1998). Thus, the effect of nutrient stratification near the soil surface could be either a negative or positive factor influencing nutrient uptake and is highly dependent on the environment. Schwab et al. (2006) used moldboard plowing to redistribute P in a number of highly stratified soils in Kansas; however, no increased yield was observed.

The advantages of band applications of starter fertilizer for corn in no-till planting systems have been discussed earlier. However, a number of studies have documented the importance of subsurface or deep banding for ridge-till and no-till planting in the northern Corn Belt (Rehm et al., 1995). However, the response to deep banding has not been universal as many studies have obtained no or mixed results in recent years. In one study, placement of P and K had a significant effect on corn yield when soil test levels for P and K were in the low range, but not when they were high. Highest yield responses generally resulted from a combination of subsurface band with a starter fertilizer (Rehm et al., 1988). In contrast, responses observed by Bordoli and Mallarino (1998) appeared more closely related to deficient rainfall in late spring and early summer than with soil test K. Often corn yield advantages to deep band placement of P and K were small (Bordoli and Mallarino, 1998; Mallarino and Murrell, 1998) and would rarely offset the higher application costs (Bordoli and Mallarino, 1998).

A similar range of response to placement of immobile nutrients has been found for other crops grown in conservation tillage production systems. Yields of grain sorghum, for example, were improved when P and K fertilizers were knifed in below

the soil surface rather than broadcast on the surface (Sweeney, 1989). Yield increases from this knife placement were larger where soil test values for P and K were in the low rather than the medium range.

Nutrient stratification has not always been associated with reduced yields and response to alternative fertilizer placement techniques, however. In a long-term tillage in Indiana, mold-board plow, chisel plow, ridge-till, and no-till systems were included, in both a continuous corn monoculture and a corn/soybean rotation (Griffith et al., 1988). Extensive stratification of P, K, and acidity, both vertical and horizontal, was found within the surface 30 cm of soil in both rotations (Cruz, 1982; Hollanda et al., 1998). However, differences in corn yields among tillage systems were relatively small in the corn/soybean rotation (<4%), but rather large differences (<17%) were found in the continuous corn yields from 1980 to 1995, indicating that stratification of nutrients alone was not a significant yield limiting factor.

Yibirin et al. (1993) evaluated the effect of mulch on the response of corn to banded K and concluded that its benefits decreased as the amount of mulch on the soil surface increased. The mulch apparently increased soil moisture and reduced soil temperature near the soil surface, thereby increasing root development and subsequent K uptake from that zone.

In contrast to other crops, yield of winter wheat grown in no till planting systems in the Great Plains was not affected by P placement when soil test values for P were in the medium range (Halvorson and Havlin, 1992). The absence of a placement effect may be a consequence of the distribution of roots closer to the soil surface when compared to the corn and grain sorghum crops and a root environment more conducive to nutrient uptake during key periods of growth.

14.5 Calcium and Magnesium

Like P and K, these nutrients are relatively immobile in most agricultural soils. In contrast to K, however, uptake of Ca and Mg by crops is considerably less. As a result, the necessity for these nutrients in fertilizer program is diminished to special or localized situations. Therefore, research that has focused on the application of these two nutrients has not been extensive.

In most agricultural soils, Ca dominates the CEC, which satisfies the Ca requirements of most crops (Mortvedt and Cox, 1985). Under acid conditions, the Ca content of the soil decreases, while the H and A1 content increases. The addition of calcitic or dolomitic limestone to correct acidity problems is the primary means by which Ca is supplied to crops. With the exception of the peanut crop (Section 11.4); Ca deficiency is much more common in fruit and vegetable crops such as tomato, apple, and lettuce (Shear, 1975).

Like Ca, availability of Mg to plants decreases under acid soil conditions due to both a pH effect and loss of Mg through leaching from the root zone (Mortvedt and Cox, 1985). Increasing the pH of the soil, even with calcitic lime, can increase Mg availability (Christenson et al., 1973). Dolomitic limestone is the preferred Mg source in areas where it is available.

Applications of MgSO₄ or KMg (SO₄)₂ fertilizers are made on low Mg soils when dolomitic lime is not available. Soil tests are commonly used to estimate the need for Mg. In the midwest United States, Mg applications for most field crops are recommended when the exchangeable Mg levels are <50 mg kg⁻¹ (Vitosh et al., 1995). General recommendations are to apply dolomitic lime if the soil is acid or to apply either 55 kg ha⁻¹ soluble Mg, or 0.5 ton dolomitic lime ha⁻¹ if the soil pH is adequate.

Since both Ca and Mg are not routinely added to fertilizer programs, the effectiveness of placement of these nutrients for agronomic crops has not been investigated. If lime is routinely used in a crop rotation, these nutrients should not generally be needed in a fertilizer program.

14.6 Micronutrients

The management of the remaining five micronutrients (Zn, Fe, Cu, and Mo), which are taken in small amounts by crop, will be discussed individually.

14.6.1 Zinc

A deficiency of Zn is most likely to occur on sandy soils formed from parent material low in Zn (Krauskopf, 1972), highly weathered tropical soils, highly calcareous soils, and organic soils (Schulte and Walsh, 1982). Overliming (Rehm and Penas, 1982), application of high rates of P (Murphy et al., 1981), and removal of surface soil by erosion, land leveling, and terracing (Frye et al., 1978; Grunes et al., 1961) are management practices that can enhance Zn deficiency.

Crops differ in their sensitivity to Zn deficiency. Corn, edible beans, and sorghum are highly sensitive; barley, sugar beet, soybean, and Sudan grass are moderately sensitive; and wheat, alfalfa, and most forage grasses are not sensitive to Zn deficiency (Laboski et al., 2006). While Zn deficiency can be corrected through either soil or foliar application, soil applications are more common for agronomic crops (Martens and Westerman, 1992) and foliar applications in the fruit and vegetable industry.

Relatively high rates of Zn, broadcast as ZnSO₄·7H₂O, are commonly used to correct a Zn deficiency in agronomic crops. Other inorganic sources include ZnO and Zn frits, which are not readily available for crop uptake unless finely ground. Application rates vary depending on the demands of the crop being grown, soil properties that could affect Zn availability, and the native supply of Zn in the soil. Higher application rates are commonly needed on calcareous than noncalcareous soils (Wiese and Penas, 1979). Higher rates are also recommended for soils with low levels of extractable Zn (Leikam et al., 2003). Lower rates of Zn are normally applied in band than broadcast applications because of the reduced Zn-soil contact, which slows the reversion of Zn to less available forms and the lowered pH in the band when Zn is applied in combination with N or N-P fertilizers. In addition to inorganic sources, a number of organic

Zn sources are used for band applications. These include Zn EDTA, Zn lignosulfate, Zn acetate, and Zn citrate. The chelated materials are commonly used for foliar applications.

14.6.2 Manganese

Manganese deficiencies in crops are found in high organic matter, slightly acidic, and poorly drained sandy soils. Soybeans, wheat, barley, and oats are highly sensitive to Mn deficiency while corn, sugar beets, alfalfa, and forage grasses are moderately sensitive (Vitosh et al., 1994). The availability of Mn is highly influenced by the total Mn content of the soil, drainage, oxidation state, SOM content, and pH. Soil pH is the most important soil property controlling the availability of Mn to plants, which decreases as pH increases. Over liming soil frequently produces Mn deficiencies (Gilbert et al., 1926; Blair and Prince, 1936; Sherman et al., 1942; Snider, 1943; Sanchez and Kamprath, 1959). The fact that Mn availability is influenced by so many factors has led to confusion concerning the effectiveness of various methods of Mn application. Positive yield responses from broadcast application of MnSO₄ or MnO, banding of Mn products at planting, banding of Mn in conjunction with an acid forming fertilizer, and foliar application of MnSO₄·7H₂O have been used successfully as a means of correcting Mn deficiencies in a number of crops (Gilbert and McLean, 1928; Evans and Purvis, 1948; Anderson and Carstens, 1973; Alley et al., 1978; Gettier et al., 1984; Mascagni and Cox, 1985a, 1985b).

Broadcast applications of Mn were found to be ineffective or less effective than banding as a means of correcting Mn deficiency across a broad range of soils (Harner, 1942; Steckel, 1946; Randall et al., 1975; Gupta, 1986; Eck, 1995). Mascagni and Cox (1985a) found that optimum yield of soybeans were obtained on Atlantic Coastal Plain soils by banding 3 kg Mn ha⁻¹ compared to broadcasting 14 kg Mn ha⁻¹. Randall et al. (1975) found similar results in Wisconsin, although an additional foliar application was required for optimum yield when deficiencies were severe. Excellent results have also been obtained when Mn is band applied in conjunction with acid forming fertilizers (Mederski et al., 1960; Petrie and Jackson, 1984) or banding an acid forming fertilizer alone (Steckel et al., 1948).

Foliar applications of Mn have also been used to correct Mn deficiency. Although applications of <1.0–5.0 kg Mn ha⁻¹ as MnSO₄·7H₂O are commonly recommended (Laboski et al., 2006; Vitosh et al., 1994), the number of applications required has not been unequivocally established. Eck (1995) found a single application of 1.1 kg Mn ha⁻¹ adequate for correcting Mn deficiency in soybeans in Indiana while Mascagni and Cox (1985a, 1985b) found that up to three applications were required.

14.6.3 Iron

Like Mn, Fe availability to plants is controlled by a number of soil factors including pH, free CaCO₃ content, SOM content, and redox potential. The reader is referred to reviews by Moraghan and Mascagni (1992) and Lindsay (1992) for a detailed discussion

of these factors. Iron deficiency (chlorosis) is common in soybeans and grain sorghum on calcareous soils (Martens and Westerman, 1992). Because of large differences in tolerance to Fe chlorosis among and within plant species, development of tolerant cultivars has been possible. Because broadcast applications of inorganic sources of Fe to the soil are not effective in controlling or correcting Fe chlorosis, foliar sprays using chelates such as iron ethylene diamine-N,N'-bis(2-hydroxyphenyl) acetic acid (FeEDDHA) are generally recommended in field crops but multiple applications may be required. Band applications of iron, the application of animal manure and seed treatments of iron have all been used successfully.

14.6.4 Copper

Copper deficiency occurs most commonly on organic soils, but can also occur where sandy soils are highly weathered, on mineral soils with a high SOM content, and on calcareous mineral soils (Martens and Westerman, 1992). Crops differ greatly in their susceptibility to Cu deficiency with wheat, oats, Sudan grass, and alfalfa being highly sensitive; barley, corn, and sugar beet moderately sensitive; and soybeans and most forage grasses tolerant to Cu deficiency (Vitosh et al., 1994).

While a number of fertilizers to supply Cu are available, CuSO₄·5H₂O is the most common fertilizer material used because of low cost and high water solubility. Karamanos et al. (1986) evaluated a number of Cu fertilizers and their effect on crop production. Copper oxide was generally ineffective in the year of application but residual effects alleviated Cu deficiency, while CuSO₄·5H₂O and chelated products were effective in the year of application. However, there was no residual effect from the application of chelated materials. Applications of animal manure or biosolids containing Cu will also correct deficiencies. Swine manure is an excellent source of Cu in many areas because of the high levels of Cu fed to growing pigs. Soil application is the preferred method of correcting Cu deficiency because of the good residual effects from Cu fertilization. Copper fertilizers are most commonly broadcast at or before planting but can also be banded. Common rates for soil application for field crops are 2.2-3.3 kg Cu ha⁻¹ banded or 33–66kg Cu ha⁻¹ broadcast (Schulte and Kelling, 1999). Foliar applications can be used during the growing season to correct Cu deficiencies with chelated materials being favored.

14.6.5 Molybdenum

Molybdenum is required for $\mathrm{NO_3}$ reduction reactions in plants and the symbiotic fixation of N by legumes. Deficiencies of this nutrient have been reported for a number of crops grown on acid soils in the Great Lakes and southern regions and coastal areas of the United States, as well as in New Zealand and Australia. Deficiencies are usually observed with the legume crops.

Molybdenum deficiencies can be corrected by liming, by soil or foliar application of Mo or with seed treatment. While Mo toxicity in plants is rare, high concentrations of Mo in forages may induce Cu deficiency in animals (Miltmore and Mason, 1971).

Therefore, care must be exercised in making Mo applications. Application methods that utilize the lowest effective Mo rate, generally seed treatment, are preferred.

15.1 Introduction

Nutrient use efficiency (NUE) is an important aspect of plant nutrient management. While discussion of NUE of all essential elements is desirable, because over 108 ton of nitrogen (N) fertilizer is produced annually, 60% of which is used in cereals, we will focus on N as an example of a mobile nutrient from both production and environmental perspectives. Phosphorus (P) will represent immobile nutrients. The importance of spatial and temporal variability on improved nutrient and water use efficiency (WUE) will also be discussed. This will highlight the need for better mid-season management practices that can ultimately decrease nutrient loss from different causes. The approaches used to improve NUE of N and P can be applied to other plant nutrients. Recent technological advances that improve WUE will be further highlighted.

15.2 Nutrient Use Efficiency

NUE can be defined in several ways (Moll et al., 1982; Gourley et al., 1994; Baligar et al., 2001; Cassman et al., 2002; Mosier et al., 2004; Fixen, 2006; Roberts, 2008) and at times some definitions are misleading. Roberts (2008) and Cassman et al. (2003) discussed different types of NUE calculations and demonstrated

each with data compiled from Asia and the United States. For example, fertilizer use efficiency of 21% or 100% can be calculated using the same input data but different computation methods (Roberts, 2008).

15.3 Bray's Nutrient Mobility Concept: What's Nutrient Efficiency Got to Do with It?

Bray's mobility concept (Bray, 1954) remains a benchmark paper for those truly interested in improving NUE of mobile and immobile nutrients. Further discussion will focus on how this has been applied in precision agriculture, and how Liebig's Law of the Minimum (van der Ploeg et al., 1999) continues to be relevant, especially for those scientists focused on yield prediction as a tool for improved nutrient management.

The term "mobility" in the field of soil fertility and plant relationships refers to the overall process whereby plant nutrient ions reach sorbing root surfaces (Bray, 1954). Bray (1954) proposed that the availability of soil nutrients for plant use might be strongly influenced by their level of mobility in the soil and classified nutrients as mobile or immobile. He also conjectured that the volume of soil from which roots sorbed nutrients also

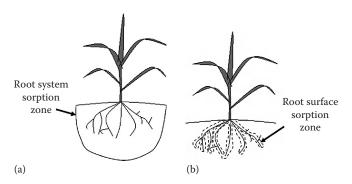

FIGURE 15.1 Root system sorption zone of mobile nutrients (a) and root surface sorption of immobile nutrients (b). (Adapted from Bray, R.H. 1954. A nutrient mobility concept of soil plant relationships. Soil Sci. 78:9–22.)

determined the soil fertility requirements of a plant. Bray's concept of soil nutrient mobility was plausible in the field of soil nutrient–plant relationships.

Bray identified two distinct types of soil sorption zones of plants. The first one is the large volume of soil occupied by the major part of the plant root system called the root system sorption zone (Figure 5.1a) from which mobile nutrients, like nitrate-N (NO_3^- –N), are taken up in large quantities by plants. This results in their "net" requirement being almost equal to the crop content at maturity. Mobile nutrients act as a "limiting nutrient" in the context of the "Law of the Minimum."

The second sorption zone is a relatively thin layer of soil adjacent to each root surface (root surface sorption zone, Figure 5.1b) from which immobile nutrients can be removed by the plant. From this zone, the roots effectively obtain relatively immobile nutrients like P. The sum of these small root surface sorption zones represents only a small part of the soil. Hence, plant roots access only a small fraction of the relatively immobile nutrients present. The amount of nutrient that must be present in the soil to support maximum crop yield is many times larger than the crop nutrient content (Cornforth, 1968). Variation in yield might affect the plant's ability to obtain the relatively immobile nutrients. However, the soil nutrient level needed to support a wide range of plant yield does not vary with yield, because the plant's ability to obtain the nutrient is proportional to its yield.

Bray's mobility concept was a combination of the Mitscherlich percent sufficiency concept (Bray, 1958; Johnson, 1991) and Liebig's Law of the Minimum. Bray showed that Liebig's Law of the Minimum concept applied for mobile nutrients like NO₃⁻-N, and that Mitscherlich's percent sufficiency concept worked for immobile nutrients like P and potassium (K). In Liebig's theory of plant response, if all nutrients were adequate except one, then yield would increase in direct proportion to increasing the availability of the deficient nutrient. Bray's concept of how plants responded to soil nutrient availability could be represented as a straight-line response for a nutrient that is 100% mobile in the soil and a curvilinear response for relatively immobile nutrients.

When plants are grown close together, as in intensive agriculture, it becomes clear that the volume of soil from which plants extract

mobile nutrients may overlap, while soil volumes supplying immobile nutrients do not. Thus, plants will compete among each other for mobile nutrients if they are closely spaced (Cornforth, 1968; Darrah et al., 2006). As cropping systems increase yield by planting more densely, there will be a direct increase in demand by the crop for the mobile nutrients and it will be necessary to add more of the mobile nutrient to eliminate the competition among plants.

On the other hand, there is no competition among plants for extracting immobile nutrients even when growing close together. This is because the plant root is extracting immobile nutrients from an extremely small volume of soil, often only the soil within a millimeter or two from the root surface (Cornforth, 1968; Eghball and Sander, 1989). As plants grow, they obtain additional supplies of an immobile nutrient by developing more roots that will explore new volumes of soil. If a soil is 100% sufficient in supplying an immobile nutrient for a dry-land crop yield of 3.8 ton ha⁻¹ corn (Zea mays L.), then it will also be 100% sufficient if the field is irrigated and the yield is 11.3 ton ha-1 (Johnson, 1991). Sufficiency of immobile nutrients is independent of yield level. The most limiting of the mobile nutrients will determine the maximum possible yield (as in Liebig's "Law of the Minimum"). Deficiencies of immobile nutrients reduce the potential yield of a site or field (Raun et al., 1998), by a "percent sufficiency" factor, and identify the ultimate potential yield.

In contrast to what Bray documented, Sollins et al. (1988) argued that there are circumstances in which mobile nutrients become immobile. They indicated that variable-charge (v-c) and permanent-charge (p-c) soils differ in the dynamics of nutrient mobility and this dynamic is more complex in v-c than in p-c soils. For example, as the pH of v-c soils decreases, cation exchange capacity (CEC) decreases and anion exchange capacity (AEC) increases. If AEC exceeds CEC, cations such as ammonium (NH₄⁺) and K considered as relatively less mobile will be more mobile than anions such as NO₃⁻.

Putting into perspective the concept of mobility of nutrients and NUE, it is clear that access of plant roots to nutrients is restricted by the mobility of a nutrient. Nutrient mobility also determines the potential for loss from the nutrient cycle, which consequently affects NUE. The efficiency of nutrient acquisition by roots is dependent on nutrient mobility. Most of the cutting edge nondestructive yield prediction methods such as sensor-based nutrient management depend heavily on this concept.

15.4 Status of Nutrient Use Efficiency

Excessive use of nutrients can lead to environmental pollution and unnecessary fertilizer cost to producers (Cassman et al., 2003). Fertilizer use efficiency (NUE of applied inorganic N, P, and K fertilizers) was reported to be about 50% or lower for N, less than 10% for P, and close to 40% for K in the 1980s (Baligar and Bennett, 1986; Shaviv and Mikkelsen, 1993). Unfortunately, fertilizer use efficiencies have not increased substantially since then. Fertilizer N recovery efficiencies from researcher managed experiments for major grain crops have been reported to range from 46% to 65% (Roberts, 2008) where crops are grown under

optimal management practices. For field managed plots, average N recovery did not surpass 30% and 40% under rainfed and irrigated conditions, respectively (Ladha et al., 2005). Globally, cereal N use efficiency is only 33% (Raun and Johnson, 1999; Davis et al., 2003). In corn and sorghum [Sorghum bicolor (L.) Moench], Muchow (1998) reported maximum N use efficiency (calculated as grain yield per unit N uptake) of 61 and 48 kg grain⁻¹ kg⁻¹ N absorbed, respectively.

Phosphorus use efficiency (PUE) is dependent on the method of placement and soil type (Peterson et al., 1981; Sander et al., 1990, 1991). Sander et al. (1990, 1991) reported that PUE averaged 8% when P was broadcast and incorporated and 16% when P was either knifed with anhydrous ammonia or applied with the seed in winter wheat (*Triticum aestivum* L.). Of course, this depends on residual soil P level (Peterson et al., 1981). Several studies (Giskin et al., 1972a, 1972b, 1972c; Bond et al., 2006) showed that P use efficiency of crops decreased with high level of soil residual P level. Residual P can be high due to high soil organic matter or high availability of P from previous applications attributed to low P fixing capacity of a soil. At both soil pH extremes where P could be precipitated, it is likely to see high crop P response, which may not translate to high PUE (Giskin et al., 1972a; Harrison and Adams, 1987).

It is worth mentioning the distinction between NUE and effectiveness. The highest NUE always occurs at the lower parts of the yield response curve, where fertilizer inputs are lowest. There must be a balance between optimal NUE and optimal crop productivity. In fact, in winter wheat, Wuest and Cassman (1992) and Sowers et al. (1994) demonstrated a decrease in N use efficiency with increased N fertilizer rates. Specifically, management systems designed for high protein harvest (Fowler, 2003) in cereals have resulted in low use efficiency since high protein harvest requires higher rates of fertilization than does grain production (Fowler et al., 1990). This suggests that effectiveness of fertilizers in increasing crop yields and optimizing farmer profitability should not be sacrificed for the sake of efficiency alone (Fixen, 2006; Roberts, 2008).

15.5 Causes of Low Nutrient Use Efficiency

One of the major causes of low NUE is the fact that the elemental cycle of most plant nutrients have sinks for loss; meaning one or more forms of a nutrient will leave the cycle through manmade or natural processes. For instance, N can be lost directly from the root system/rhizosphere area by denitrification, volatilization, and leaching or after plant uptake, by ammonia (NH₃) volatilization from plant tissues. Nitrogen losses via denitrification range from 10% to 70% of applied fertilizer N resulting in reduced efficiency (Avalakki et al., 1995; Jambert et al., 1997; Pu et al., 1999). According to Pu et al. (1999), denitrification is a major problem when large amounts of residue are left on the soil. Likewise, Hargrove and Kissel (1979) reported that in a laboratory study using urea, 13%-31% of the applied N was lost as NH₃. Hamid and Mahler (1994) and Mahler and Hamid (1994) reported 4.9%-37.8% loss of surface applied urea fertilizer to the atmosphere through NH3 volatilization in Northern Idaho soils. Nitrate leaching occurs more so in well-drained soils than poorly-drained soils and when precipitation/irrigation water exceeds water storage capacity (Stout et al., 2000). Leaching losses increase with increased fertilizer rate especially when the N application rate exceeds the amount required for optimum crop growth (Hauck and Tanji, 1982). Estimates of NO₃⁻ leaching from different soils and cropping systems ranged from 4 to 80 kg ha⁻¹ year⁻¹ (Hauck and Tanji, 1982; Dowdell et al., 1984; Jemison and Fox, 1994; Davis et al., 2003).

Ammonia losses to the atmosphere from plant tissues can contribute substantially to decreases in N use efficiency. Francis et al. (1993) reported that 52%–73% of the total unaccounted N was attributed to loss of NH₃ from plant tissue. The authors further showed that N loss from plants increased from 49 to 78 kg N ha⁻¹ as N fertilizer rate increased from 50 to 150 kg N ha⁻¹ (with 50 kg N ha⁻¹ increment). Lees et al. (2000) estimated net plant N loss (determined as the difference of forage N uptake at flowering from total N in the grain and straw at maturity) of 3–42 kg N ha⁻¹. They also found that plant N loss was highest for the highest N rate. Similarly in wheat, Harper et al. (1987) reported that 21% of applied fertilizer N was lost as NH₃, of which 11.4% was from the soil and plant soon after fertilization, and 9.8% from leaves between anthesis and maturity.

Phosphorus fixation by Fe and Al oxides in acid soils and by Ca in alkaline soils and loss of P by erosion in all soils contribute to low PUE. PUE is improved by maintaining soil pH in the optimum range (Blair et al., 1971) to minimize these P fixation reactions. For P, the amount needed to satisfy the precipitation reactions in soils prone to P fixation is a major problem for increasing its use efficiency. It has been reported that only 20%-30% of the P fertilizer applied will be available for crop use and the percentage decreases the longer P is in contact with the soil before plant uptake can occur (Janssen et al., 1987). Soil inorganic P undergoes a very complex system of reactions and compound formation depending on soil pH, type and amount of soil minerals, amount of P in the soil, and several other factors (Sharpley and Sisak, 1997; Slaton et al., 2002). To improve PUE with a reduced input of fertilizer, it is necessary to first develop a strategy to reduce the amount of P fertilizer fixed (Jarvis and Bolland, 1991; Helyar, 1998). Phosphorus fertilizer placement could be critical due to the limited root surface sorption zone as demonstrated by Bray (1954).

15.6 Strategies to Improve Nutrient Use Efficiency

Improving NUE requires the development and adoption of integrated crop and nutrient management methods (Alcoz and Hons, 1993; Arregui and Quemada, 2008) in a sustainable way. Such methods include:

 Appropriate fertilizer application rate (Cochran et al., 1978; Campbell et al., 1993), timing (Bundy, 1986; Shanahan et al., 2004), placement methods (Black and Reitz, 1972; Mahler et al., 1994; Barbieri et al., 2008), and sources (Pan et al., 1984; Salsac et al., 1987; Huffman, 1989)

- Use of inhibitors for N fertilizer (Bremner and Douglas, 1973; Schlegel et al., 1986; Shaviv and Mikkelsen, 1993)
- Foliar applications (Dion et al., 1949; Harder et al., 1982; Mosali et al., 2006; Girma et al., 2007b)
- Cover crops and crop rotations (Raun and Johnson, 1999; Schomberg et al., 2006)
- Tissue and sensor based nutrient management methods (Blackmer et al., 1994; Stone et al., 1996; Raun et al., 2002)
- Use of traditional crop breeding and biotechnology (Kamprath et al., 1982; Bufogle et al., 1997; Kanampiu et al., 1997)

The different methods that must be integrated to maximize NUE are discussed in detail next.

15.6.1 Adjusting Rate, Timing, Placement, and Source of Fertilizer Application to Increase Nutrient Use Efficiency

15.6.1.1 Rate of Nutrient Application

Fertilizer application rate plays an important role in NUE but should be combined with other methods designed to improve NUE. In response to efficiency, environmental, and economic concerns, researchers made significant progress in improving optimum fertilizer rates. Fertilizer application rate evolved from less accurate blanket "recommendation domain," based to site-specific variable rate application (VRA) systems today. Regardless, all fertilizer rates are determined from measurements taken from soil, crop or both.

Worldwide statistical-based nutrient response curves have been widely used for establishing optimum fertilizer rate. Linear or quadratic nutrient response curves and their variants such as liner-plateau, linear-linear, and quadratic-plateau have been fitted to yield data (Neeteson and Wadman, 1987; Cerrato and Blackmer, 1990; Bullock and Bullock, 1994; Girma et al., 2007c). Other nutrient response curve models were also tested but found to be unreliable. For example, for potato (Solanum tuberosum L.), Bélanger et al. (2000) compared quadratic, exponential, and square root response models and found that both exponential and square root models were weaker than the quadratic model in determining economically optimum N rate in Atlantic Canada. This approach is affected by temporal and spatial variability (Bullock and Bullock, 1994; Makowski et al., 2001; Liang et al., 2008), varies with change in price of both fertilizer and economic yield (Babcock, 1992), and would not help for in-season fertilization decision. Mechanistic models were also evaluated for predicting N fertilizer requirements (Geist et al., 1970) but were not adopted simply because they were based on too many theoretical assumptions and were not user friendly.

Soil test-based N and P recommendation has been employed in many parts of the United States and elsewhere. For N, total soil N or soil test $\mathrm{NO_3}^-$ (Soltanpour et al., 1989) were widely used. Two types of soil test $\mathrm{NO_3}^-$, namely, preplant soil $\mathrm{NO_3}^-$ -N test (PPNT) and presidedress soil $\mathrm{NO_3}^-$ -N test (PSNT) were

employed for drier (Bundy and Meisinger, 1994) and humid areas (Meisinger et al., 1992; Andraski and Bundy, 2002) of corn growing states, respectively. However, PSNT was criticized for lack of correlation with actual crop response and nutrient demand, and resulted in large variability (Andraski and Bundy, 2002). More importantly, the method failed to identify non-N responsive soils when applied to different soils. To overcome these problems, the Illinois soil N test (ISNT) method was developed. This method employs diffusion analytical procedure to measure alkali-hydrolyzable amino sugar, which was highly and inversely correlated with fertilizer N response of corn yield (Khan et al., 2001; Mulvaney et al., 2001). This method has been reported to work in several corn growing states (Khan et al., 2001; Mulvaney et al., 2005; Williams et al., 2007). Yet, in other areas, the method did not improve the prediction of fertilizer N requirements (Barker et al., 2006; Marriott and Wander, 2006; Laboski et al., 2008; Osterhaus et al., 2008) or found to be as good as total soil N (Spargo et al., 2009).

Since the last 20 years, the focus of nutrient rate determination shifted to in-season application rate methods aided by destructive and nondestructive plant tissue analysis (Turner and Jund, 1991; Scharf et al., 2006; Hawkins et al., 2007; Zhang et al., 2008), soil test, and remote sensing (Solie et al., 1996; Raun et al., 2001; Barker and Sawyer, 2010). The latter will be discussed in detail under "sensor-based variable rate nutrient management." Soil test methods such as ISNT discussed above are useful but less convenient for producers as the methods require laboratory testing that might take time. Soil testing remains one of the most accurate methods for determining nutrient requirements, however. At the heart of each in-season N rate decision tool is a level of spatial and temporal accuracy of measurements that aide in increasing NUE of crops. Nondestructive in-season tissue analysis methods used instruments such as chlorophyll meters. Chlorophyll meter readings were correlated with soil NO₃- or plant tissue N concentration to estimate nutrient needs of crops thereby improving NUE. Both success (Schepers et al., 1992; Hussain et al., 2000) and lack of success (Piekkielek and Fox, 1992; Bavec and Bavec, 2001) with this method were reported. In paddy rice (Oryza sativa L.) in the Philippines, greater agronomic efficiency of N fertilizer was obtained with the use of chlorophyll meter sufficiency indices compared with preset timing schemes commonly practiced (Hussain et al., 2000). A study conducted in corn growing areas of north-central United States concluded that chlorophyll meter readings were strongly related ($R^2 = 0.53-0.79$) with economical optimum N rate (EONR) and suggested the method can be applied with reasonable accuracy in wide range of environments (Scharf et al., 2006). Unlike these reports, Piekkielek and Fox (1992) and Bavec and Bavec (2001) showed that the relationship between chlorophyll meter reading and grain yield was weak and growth stage dependent. According to Waskom et al. (1996) portable chlorophyll meter was effective for determining N need but must be accompanied by soil test to determine actual N. Schepers et al. (1992) and Hawkins et al. (2007) used relative chlorophyll meter values to establish N rates in corn.

15.6.1.2 Time of Nutrient Application

The time of application of fertilizer has a significant role in achieving increased NUE for both mobile and immobile nutrients. Providing a mobile nutrient, like N, just prior to a plant's rapid uptake phase increases NUE. The growth stages at which rapid N uptake occurs are well defined for cereals. For winter wheat, Girma et al. (2011) reported that more than 61% of the maximum total N accumulated at later stages of growth could be accounted for by Zadoks 30 (pseudostem) growth stage. Therefore, in wheat, Zadoks 30–32 (2 nodes detectable) was the best time to topdress N to increase use efficiency and optimize final yield (Raun and Johnson, 1999; Girma et al., 2011).

In corn, a steady increase in dry matter (DM) and N accumulation was observed between the V4 (4th leaf collar fully unfolded) and V8 (8th leaf collar fully unfolded) corn growth stages, after which a fast increase in N uptake was measured between V8 and R2 (blister) (Shanahan et al., 2004). Walsh (2006) recommended topdressing/sidedressing N at or before the V10 (10th leaf collar fully unfolded) growth stage to supply the growing corn with adequate N when it is required in the greatest quantities. Similarly, Ma et al. (1999) reported that only a limited amount (20%) of the total plant N was accumulated by V6 (6th leaf collar fully unfolded), and most of the N (60%) was accumulated between V6 and R1 (silking stage). Three studies, Licht and Al-Kaisi (2005), Freeman et al. (2007a), and Girma et al. (2011), reported that greater than half of the total N was accumulated between V8 and VT (tasseling) in corn. These research findings suggest that topdressing or splitting N between V8 and VT growth stages in corn can increase N use efficiency.

Applying a small portion of the N at planting and the remainder of the N just before the rapid growth phase in the spring (a split application) was effective for increasing N use efficiency of wheat (Alcoz and Hons, 1993; Mahler et al., 1994). López-Bellido et al. (2006) reported that in spring wheat, preplant application of 150 kg N ha⁻¹ resulted in 13% recovery of N fertilizer, while recovery was as high as 42% when applied at the beginning of stem elongation. For winter cereal crops grown in dry climates, splitting N applications may not increase N use efficiency because N losses are minimal (Arregui and Quemada, 2008). Similarly, in Minnesota, Jokela and Randall (1997) found that nonirrigated corn did not respond to timing of fertilizer N application.

Synchronizing time of N fertilizer with peak crop demand reduces N loss to the environment as well as improves crop yield and N use efficiency (Randall et al., 1997; Karlen et al., 1998). Preplant application of fertilizer especially several months before planting does not seem rational in relation to fertilizer dynamics in the soil. From an environmental health perspective, sidedressing N midseason can significantly reduce NO_3^- leaching into ground water (Bundy, 1986). Also, sidedress N reduces the N that can move by runoff into watersheds impairing quality of surface waters (Allen, 2002). According to Sanchez and Blackmer (1988), 50%–60% of fall-applied N fertilizer is lost from the soil through several of the pathways that lead to N loss from the soil. A winter wheat study conducted to assess the effect

of split N applications on N use efficiency using ¹⁵N showed that splitting recovered 7%–16% more fertilizer than fall applications (Sowers et al., 1994).

15.6.1.3 Placement of Nutrient

For both mobile and immobile nutrients, the method of application and placement significantly influences the efficiency of the nutrient (Mahler et al., 1994; Barbieri et al., 2008; Kapoor et al., 2008). Generally, subsurface or surface band applications of solid urea and urea ammonium nitrate (UAN) liquid fertilizers in high residue cropping systems can be used to avoid N tie-up in crop residues or N loss by NH₃ volatilization (Mahler et al., 1994). Incorporation of broadcast urea, UAN, and manure into the soil where tillage is practiced can assist in avoiding NH₃ volatilization and run-off losses (Campbell et al., 1993; Freeman et al., 2007b). Banding P is the best strategy instead of broadcasting (Bordoli and Mallarino, 1998).

Tillage and crop residue greatly influence NUE, especially for N. In a no-tillage production system, grain yield improved by 32% when 60 kg N ha⁻¹ was banded 8-10 cm below the seed row and 15% when banded between the rows compared to surface broadcast urea (Rao and Dao, 1996). Adaptation of subsurface placement of N fertilizer for no-till winter wheat has the potential to significantly improve N availability to plants and thereby improving N use efficiency and reducing environmental and economic risks (Rao and Dao, 1996). Similarly, crop residue can increase or decrease NUE based on the quantity of residue retained, and type of crop and tillage (Eagle et al., 2000; Kravchenko and Thelen, 2007). In rice, Eagle et al. (2000) reported that straw retention lowered N use efficiency compared with straw removal or burning. Of course, in a no-till setting with total or partial residue retention, fertilizer N use efficiency could be low due to immobilization (Black and Reitz, 1972).

For immobile nutrients the application of all fertilizer at planting is a common practice. NUE can be improved by placing the fertilizer close to the root sorption zone in bands (Sanchez et al., 1991; Jacobsen et al., 1997). PUE is lower when broadcast, compared to banded, because of greater fixation of soluble fertilizer P when broadcast or due to low soil test P (Bell and Black, 1970). For sweet corn (Sanchez et al., 1991) in a low soil test P soils, the relative P fertilizer efficiency was greater than 3:1 for band to broadcast ratio. However, some reports refute the advantage of banding over broadcast P (Borges and Mallarino, 2001, 2003). Borges and Mallarino (2001) found little difference between broadcast and band P on yield and P uptake of corn. In a soybean study, band P had higher P uptake than broadcast for only 3 out of 14 sites (Borges and Mallarino, 2003).

15.6.1.4 Source of Nutrients

Another factor that has a considerable effect on NUE is the nutrient source or form used, which determines the risk of loss and availability of the nutrient. It has been generally agreed that maintaining N in the immobile NH_4^+ form, rather than in the

mobile NO₃⁻ form, will increase N use efficiency. Tsai et al. (1992) suggested that the use of NH₄⁺–N fertilizers can reduce leaching and denitrification losses and allow extended availability for late season uptake. Uptake was increased by 35% when N was supplied as NH₄⁺ based N sources (Wang and Below, 1992). The N use efficiency of NH₄⁺–N based N fertilization has been tied to reduced energy cost for assimilation in an actively growing corn crop compared with NO₃⁻–N (Pan et al., 1984; Salsac et al., 1987; Huffman, 1989; Randall and Mulla, 2001). While source of fertilizer plays a crucial role in improving NUE, it should be used as a component of a sustainable nutrient management plan and not as a sole strategy as presented in most reports.

15.6.2 Urease and Nitrification Inhibitors for N Fertilizers

A strategy for slowing down urea hydrolysis and nitrification has been recommended as a method to improve N use efficiency of urea containing fertilizers (Shaviv and Mikkelsen, 1993). Urease inhibitors were reported to delay urea hydrolysis in soils and reduce gaseous loss of urea N as NH₃ (Bremner and Douglas, 1973; Schlegel et al., 1986). Bremner and Douglas (1973) showed that gaseous loss of urea N as NH₃ from urea applied on sandy soil incubated at 20°C for 14 days was reduced from 61% to 0.3% by addition of 2,5-dimethyl-p benzoquinone inhibitor. Likewise, using ammonium lignosulfonate as a urease inhibitor, NH₃ loss from surface-applied urea was reduced up to 85% of the amount lost with plain urea (Al-Kanani et al., 1994).

Nitrification inhibitors (NIs) slow the soil conversion of the less mobile NH₄+-N form to the leachable NO₃--N form. These compounds are especially useful on coarse textured soils where leaching is likely and on fine textured soils where excess water can cause denitrification losses of NO3-N (Shi and Norton, 2000). The use of an NI can be helpful with both preplant and sidedressed N applications. In spring wheat in the northern Great Plains, Goos and Johnson (1999) reported that the apparent N uptake efficiency of grain and straw was 50%-56% with the use of nitrapyrin and ammonium thiosulfate as NI compared to 24% for the control. In corn, Walters and Malzer (1990) reported a significant improvement in N fertilizer use efficiency with NI with the application of 90 kg N ha-1 as urea. The use of inhibitors as effective tools for reducing N loss requires certain conditions to be fulfilled. However, the use of inhibitors by themselves may not always translate to improved efficiency. For example, a study in winter wheat and barley (Hordeum vulgare L.) revealed that use of fertilizer with an NI (3,4-dimethylpyrazole phosphate, DMPP) did not improve N use efficiency (Arregui and Quemada, 2008).

15.6.3 Foliar Fertilization for Improving Nutrient Use Efficiency

It has been more than six decades since scientists proved the benefits of foliar uptake of nutrients through leaves and other green tissue parts using radioactive and isotopically tagged nutrients (Dion et al., 1949). Studies showed foliar fertilization is more efficient and reduces potential environmental impact than soil fertilization (Harder et al., 1982; Mosali et al., 2006; Girma et al., 2007b). Dixon (2003) reported that foliar-applied nutrients can be 4–30 times more effective than soil applied nutrients. This high efficiency is related to increased enzymatic activities in plant cells with foliar application. Others reported that foliar fertilization was 8–10 times more efficient than root uptake (Wittwer et al., 1963). Foliar applications have provided a highly efficient alternative for supplying nutrients to plants, particularly micronutrients, which are needed in small quantities and are subject to reduced availability when soil applied.

At present, foliar N in corn is not a viable option because of the higher temperatures present throughout the growing season. Liquid N fertilizer sources, such as UAN, adhere to the leaf, when applied directly to the leaves. This coupled with the high temperature of the summer can result in leaf burn (Lohry, 2001). However, many new products are currently available that can be applied foliar, and that have limited leaf burn including urea triazone and urea formaldehyde solutions. In corn, the alternative to foliar application to increase NUE is a traditional sidedress application.

Foliar P fertilization can increase P use efficiency in comparison to soil-applied P because P fixation in the soil is avoided. Averaged over 6 site years, Mosali et al. (2006) reported 80% PUE in winter wheat when applied foliarly at 2 kg P ha⁻¹ between stem elongation and heading. Similarly, in rainfed corn, Girma et al. (2006) reported 35% more PUE than soil applications of P when 2 kg P ha⁻¹ was applied to the foliage at the V8 growth stage of corn. With new fertilizer formulations and application technologies, the use of foliar fertilization to increase NUE tool may increase in the future.

15.6.4 Use of Cover Crops and Crop Rotation

The use of winter cover crops can help prevent NO₃-N leaching in high rainfall areas. Cover crops absorb residual nutrients and return them to the soil for the following crop. Guillard et al. (1995) found that N use efficiency was increased in cornrye (Secale cereale M. Bieb) and oat (Avena sativa L.)-tyfon (Brassica spp.) cropping systems with the application of 112 kg N ha-1. Pikul et al. (2005) reported N use efficiency of 49, 67, and 70 kg corn grain yield kg-1 N for continuous corn, cornsoybean (Glycine max L. (Merr.)), and corn-soybean-wheat-alfalfa (Medicago sativa L.) rotation systems, respectively, with application of moderate N (N rate predicted to achieve 5.3 Mg ha-1 corn yield). In irrigated or high-rainfall production regions, soybeancorn rotations have high N use efficiency and can reduce the amount of residual N available for leaching when compared to continuous corn (Huang et al., 1996). Unfortunately, rotations are not easily adopted by farmers who have become accustomed to monoculture production systems since a new crop often requires purchase of additional equipment and learning to integrate new cultural practices. In irrigated agriculture, the use of high N rates as a substitute for more N use efficient rotation systems (corn-soybean) must be weighed against the increased potential for NO₃-N loss (Anderson et al., 1997).

Nitrogen use efficiency for wheat following legumes was 32% and 21% greater than that of wheat following fallow and continuous wheat, respectively (Badaruddin and Meyer, 1994). In another study, Badaruddin and Meyer (1990) found that N use efficiency of wheat was greater following alfalfa or hairy vetch (Vicia villosa Roth.) green manure crops than fallow. Average corn N use efficiency derived from soybean and alfalfa residue for the whole plant and grain was 43% and 30%, respectively, (Hesterman et al., 1987). Wheat-corn-fallow production systems are promoted instead of wheat-fallow where only 420 mm precipitation is received per year (Kolberg et al., 1996). The more intensive systems (growing more crops in a given period of time), require greater fertilizer N inputs but are higher in total yield and economically advantageous (Kolberg et al., 1996; Anderson, 2005). More intensive dryland cropping systems lead to increased WUE and better maintained soil quality (Halvorson and Reule, 1994; Anderson, 2005). Alternative dryland systems proposed include spring barley, corn, and winter wheat grown in rotation with adequate N fertilization instead of continuous winter wheat-fallow (Halvorson and Reule, 1994).

15.6.5 Sensor-Based Variable Rate Nutrient Management

Sensor-based variable rate nutrient management employs spectral radiance in red and near-infrared (NIR) regions of the electromagnetic spectrum as a tool to detect the health of an actively growing plant (Lukina et al., 2001). This tool was introduced in nutrient management for cereals particularly in wheat and corn in the mid-1990s. Blackmer et al. (1994) found strong correlation between reflected radiation and relative grain yield at later vegetative growth stages. Stone et al. (1996) demonstrated that an index developed from red and NIR reflectance could be an excellent predictor of total N uptake of a crop at early stages of winter wheat growth. This technique allowed the accurate prediction of fertilizer N requirement, thus improving crop N use efficiency (Raun et al., 2002; Teal et al., 2006).

The technologies that emerged from measurement of normalized difference vegetation index (NDVI), the Greenseeker® (Trimble Navigation Limited, Sunnyvale, CA), and Crop Circle™ (Holland Scientific, Inc., Lincoln, NE) sensors have a functional algorithm developed from measurements based on yield potential and responsiveness of the crop to N fertilization (Johnson and Raun, 2003; Mullen et al., 2003; Solari et al., 2008; Sripada et al., 2008). The specific growth stages at which N uptake and N use efficiency increased have been identified. Accordingly, for winter wheat, the stage between Zadoks 30 and 32 is recommended. In corn, sensor measurements were well correlated with predicted yield when measurements were obtained between V8 and V12 (Teal et al., 2006; Freeman et al., 2007a). Using this technology, N use efficiency in wheat was increased by 10%-20% and savings in fertilizer was about \$20 ha⁻¹ (Raun et al., 2009). Research in China found that a sensor-based system for determining optimum N rate for winter wheat resulted in 61% N use efficiency, surpassing the soil test-based and farmer methods by about 10% and 48%, respectively (Li et al., 2009).

The variable rate sensor-based system can be used to manage both temporal and spatial variations, which directly influence NUE. It was reported, following extensive soil sampling, optical sensor measurements of plants, and geostatistical analysis, that the spatial scale of N availability in wheat was about 1 m² (Raun et al., 1998, 2002; Chung et al., 2008). When N management decisions are made on areas of <1 m², the variability that is present beyond that resolution can be detected using optical sensors (Solie et al., 1996; Stone et al., 1996). Simple methods that can manage temporal variability and increase N use efficiency have also been evaluated. The N-rich strip or N reference strip is becoming instrumental since it is simple and can be used with or without a sensor (Girma et al., 2007a; Raun et al., 2008).

Although the use of optical sensors for improving N use efficiency has shown great promise, and there is no doubt about its contribution to improving N use efficiency, the need to develop empirical algorithms for use on different soil types, crop management systems, and climates has limited its adoption (Samborski et al., 2009).

15.6.6 Biotechnology and Variety Selection for Improving NUE

NUE is under genetic and physiological influence of a given crop and is modified by the environment (Baligar et al., 2001). Both biotech and conventional breeding can be used to identify or modify plant traits that can contribute to improvement in NUE. However, there is not much data available in this regard. The early study of N use efficiency was facilitated by identifying individual components that elucidated both uptake and utilization efficiency (Bruetsch and Estes, 1976; Moll et al., 1982). Differences among corn hybrids for N use efficiency are largely due to variation in the utilization of accumulated N before anthesis, especially under low N supply (Moll et al., 1982; Eghball and Maranville, 1991).

Wheat varieties with a high harvest index (grain produced divided by the total dry biomass) and low forage yield have low plant N loss and increased N use efficiency (Kanampiu et al., 1997). Furthermore, N assimilation after anthesis is needed to achieve high wheat yields (Cox et al., 1985) and high N use efficiency. Higher N use efficiency has also been observed in rice varieties with high harvest index (Bufogle et al., 1997). Work by Karrou and Maranville (1993) suggested that wheat varieties that produce more seedling DM with greater N accumulation are not necessarily the ones that use N more efficiently. Genetic selection is often conducted with high fertilizer N input in order to eliminate N as a variable; however, this can mask efficiency differences among genotypes to accumulate and utilize N to produce grain (Kamprath et al., 1982). This is consistent with Earl and Ausubel (1983), noting that high yielding varieties of corn, wheat, and rice released during the Green Revolution were selected to respond to high N inputs. Consequently, continued efforts are needed where plant selection is accomplished under low N, often not considered to be a priority by plant breeders and uncharacteristic of agricultural experiment stations.

15.7 Water Use Efficiency

Water is the single most important regional and global resource management challenge. In rainfed regions, water runoff, surface evaporation, low soil water holding capacity, and random precipitation are major problems constraining WUE among many factors (Kemper, 1993; Hatfield et al., 2001; Condon et al., 2002). Despite its wide use, the word WUE does not reflect losses for which intervention strategies are being developed. Some prefer to use the term "biomass to water ratio (BWR)" to reflect the biomass produced per unit of water used by a crop (Morison et al., 2008). But more importantly, the variation in units used to describe WUE when the term is used in association with different spatial and temporal scales as well as type of yield (biological or economic) calls for careful interpretation of WUE values.

Generally, WUE is the ratio between the amount of water that is used for an intended purpose and the total amount of water input within a spatial domain of interest (Guerra et al., 1998). In this review, we are interested in WUE as it is related to crop biomass production (total DM or economic yield). In view of this, the definition given by Viets (1962) and later modified by Tanner and Jury (1976) is appropriate. Accordingly, WUE is defined as

$$WUE = \frac{Dry matter or economic crop yield}{Water used to produce the economic yield}$$
(15.1)

The unit for this computation is usually kg m^{-3} .

According to World Water Assessment Program (WWAP, 2009), agricultural use accounts for 70% of freshwater withdrawals from different sources. It has been quantified that the process of photosynthesis takes 400–2000 L (average of 1600 L) of evapotranspiration (ET) to produce 1kg of wheat crop (CAWMA, 2007) depending on climatic conditions and the genetics of crop cultivars. Given this, crop WUE has doubled in the last 40 years (CAWMA, 2007).

It is anticipated that agricultural WUE will improve from 52% in 2003 to 66% in 2050 (FAO, 2008). During the same period, crop water consumption will increase by 64%-83%; almost doubling from its current annual consumption of 7130 km³ (CAWMA, 2007) due to changing weather conditions characterized by unpredictable growing seasons (FAO, 2006). However, population growth, urban expansion, bioenergy, and other economic developments are decreasing the quantity of water available for agricultural use (Müller et al., 2008). Quality of water due to salinization of ground and surface water remains a major problem. In the United States, about 87.5% of crop production is rainfed and this constitutes about 32% of arable land (World Bank, 2007). This clearly demonstrates the need to improve the WUE of this large sector. Current and future water use strategy in crop production must account for these emerging global undertakings (Angus and van Herwaarden, 2001).

15.8 Critical Factors Affecting Water Use Efficiency by Crops

There is not a single factor that controls WUE of crops. It is rather many factors that interactively and simultaneously influence water use. Soil physical and chemical properties (e.g., texture, structure, water holding capacity, salinity, and organic matter), soil management practices (e.g., tillage, residue management, planting date, etc.,), crop and crop genetics, as well as climate are among the factors that determine WUE. However, climate is likely the most influential variable. Seasonal distribution and amount of rainfall, wind, and light intensity are some of the climatic factors that limit WUE by crops. In wheat in Argentina, Abbate et al. (2004) found that WUE was greater when water was limited due to shortage of rainfall than when adequate. They hypothesized that this could be due to stomatal closure when vapor pressure deficit was highest. Genetics (crops and varieties of crops) is another factor that determines the amount of water that can be efficiently used for production of DM. Although crops adapt to specific growing conditions in a given agroecology, some are better users of available water and more efficient in translating it to DM than others (Richards, 2004; Bessembinder et al., 2005; Mueller et al., 2005). For example, Bessembinder et al. (2005) attributed the WUE of crops to their morphology (e.g., leaf angle), anatomy (e.g., leaf cuticle composition), phonology (e.g., growing degree days), and physiology (e.g., protein and fat concentration in different plant parts).

15.9 Strategies to Improve Water Use Efficiency

It is intuitive that it is not possible to manipulate climate but what is possible is to manipulate soil conditions and crop and variety traits to better cope with changes in climate and increased WUE. Therefore, strategies to increase WUE by crops should employ soil and crop management practices and genetic improvements of crops and crop varieties. The intervention needed varies for irrigated and dryland systems. For example, in an irrigated setting, WUE can be achieved by increasing the output per unit of water, reducing losses of water to unusable sinks, reducing water degradation, and reallocating water to higher priority uses (Howell, 2001). In dryland systems, soil and crop management practices can be used to conserve and increase WUE.

15.9.1 Tillage and Residue Management

Conservation tillage, crop residue management, and mulch play a pivotal role in water conservation and improving crop water use. In addition to its benefit for building soil organic matter and reducing soil erosion, no-till has emerged as a useful practice for conserving soil moisture when practiced with appropriate cultural practices (Machado et al., 2008). Such cultural practices include row spacing and seeding rate. For example, WUE was increased by 6% with row spacing of 9 cm compared to 36 cm

in no-till wheat (Tompkins et al., 1991). These authors investigated the interaction of seeding rate and row spacing on WUE under no-till and found 9 kg grain yield cm⁻¹ higher WUE with seeding rate of 140 kg ha⁻¹ and 9 cm row spacing compared to 35 kg ha⁻¹ seeding rate and 36 cm row spacing. In corn, no-till increased WUE by 0.96 kg grain yield ha⁻¹ mm⁻¹ (Norwood, 2000) suggesting reduced irrigation water demand. Reduced tillage and residue retention improved infiltration and enhanced storage of precipitation that in turn increased DM produced per unit of water.

Mulching can improve WUE through its effect on increased water storage of a soil and reduction of evaporation from surface soil. Ji and Unger (2001) found that mulched soils had 10% higher water storage capacity than bare soils when 5 mm simulated rain was applied with ET of 6 mm day-1. They further showed that 2 Mg ha-1 mulch is needed to maintain 10% or more water storage with simulated rain water of 10 mm and ET of 12 mm day⁻¹. Similarly, in north China, Zhang et al. (2005) reported that over 12 seasons, mulching improved WUE of corn by 8%–10%. The timing of irrigation also increased WUE for corn and winter wheat in this environment, where 73% of 480 mm precipitation falls during the winter wheat cropping season (Zhang et al., 2005). Beginning irrigation at jointing stage of winter wheat was preferable as prejointing irrigation of all tillers including infertile tillers could reduce crop WUE. However, in a more arid Arizona environment (277 mm seasonal precipitation), irrigation may not be delayed until jointing without yield penalty (Jama and Ottman, 1993). Burning of stubble had no effect on WUE of double cropped wheat and soybean (Daniels and Scott, 1991). In Washington, the interaction of crop residue and tillage showed that soil-stored water level was the same when conventional or no-till were practiced following undisturbed standing wheat residue in the winter (Kennedy and Schillinger, 2006). In a grain sorghum study, Unger and Jones (1981) reported that averaged over 3 years, 8 ton ha⁻¹ straw mulch increased WUE by 19% compared with no mulch. These findings suggest that surface residue retention and the amount of soil disturbance are key factors in water conservation.

15.9.2 Crop Rotations Cover Crops and Fallow System

In many parts of the United States, double cropping and other alternatives to continuous corn have been evaluated. Crop-fallow systems have been effective in conserving precipitation water for subsequent crops, in a way, contributing to higher WUE. However, the newer cropping systems can also be as good as or even better than the crop-fallow system in conserving water. In the central Great Plains, Tanaka et al. (2005) reported that wheat WUE was improved 18%–56% with the inclusion of broadleaf crops in a grass-based system. However, in a study designed to identify the most water efficient production system in Texas, Jones and Popham (1997) found that soil water content at planting of

the next crop in no-till was increased by 29 mm in a continuous wheat cropping system compared with stubble mulch.

In a study that compared forage and grain systems, Nielsen et al. (2005) found that WUE (kg DM ha⁻¹ mm⁻¹) was highest for pea followed by millet and lowest for corn. However, corn grain WUE was second to millet while pea had the lowest grain WUE. In Mediterranean environment, rotation involving barley and wheat with rapeseed (*Brassica napus* L.) and vetch (*Vicia sativa* L.) increased biomass WUE by 7 kg DM mm⁻¹ ha⁻¹ compared with monoculture barley (Álvaro-Fuentes et al., 2009). Also, precipitation use efficiency is greater for corn grown in rotation when compared to continuous corn (Varvel, 1994).

15.9.3 Crop/Variety/Hybrid Selection

Crop improvement through conventional breeding coupled with appropriate agronomic management has significantly contributed to increased water use by crops and crop varieties under both rainfed and irrigation systems (Richards et al., 2002). However, much work is needed to identify specific physiological and agronomic traits that can significantly control water utilization in crops.

It is a well-established fact that crops vary in their ability to extract soil water and reduce transpiration allowing them to survive in dry environments. In dryland areas of the Great Plains, sorghum and sunflower (*Helianthus annuus* L.) removed 19 mm more water from subsurface soil compared with corn and soybean (Norwood, 1999).

Howell et al. (1998) did not find a difference in grain and DM WUE of two corn hybrids (short and full season) but seasonal ET was reduced with a short season hybrid by 129 mm compared with a full season hybrid. In grain sorghum, Unger (1991) found that hybrids significantly differ in WUE. He concluded that highest yielding cultivar had the highest WUE.

Molecular biology could play a significant role in untangling this in the future. In Australia, isotope discrimination techniques had helped in identifying varieties with high transpiration efficiency (Richards, 2004). Other traits that could be sources of WUE improvement include increased root length (Proffitt et al., 1985; Payne, 2000; Ehdaie et al., 2003) and leaf canopy architecture (Schakel and Hall, 1979; Osborne et al., 1998). Under drought conditions, leaflets of cowpeas [Vigna unguiculata (L.) Walp] positioned paraheliotropically (becoming more vertical) in the afternoon to reduce transpiration (Schakel and Hall, 1979). Recently, in rice, researchers identified a mutant that reduced the indole-3-acetic acid (IAA) at the lamina joint, shoot base, and nodes enhancing drought tolerance (Zhang et al., 2009).

15.9.4 Soil Physical and Chemical Properties

Soil physical and chemical properties play a crucial role in soil water conservation and WUE in crops. For example, two decades ago, Stout et al. (1988) studied the effect of N supply and

soil physical properties on WUE in tall fescue (*Festuca arundinacea* Schreb.). They found that when rainfall was adequate and evenly distributed over the crop growing season, N supply controlled WUE. In contrast, when rainfall was erratic, water holding capacity controlled WUE.

Soil organic matter is a critical component of soil that "conditions" soil, improving water infiltration rate and water-holding capacity. It serves as a reservoir of water and supplies them to crops when needed, indirectly increasing WUE of crops. With a high level of organic matter soil tilth is improved, and aggregate size tends to be large and bulk density low (Allison, 1973; Six et al., 1998).

Water use by crops is influenced by salt level in irrigation water and the soil itself. In arid climates, irrigation water usually contains a large quantity of salts that over time accumulate in the soil and limit water availability in the root zone. Various strategies have been proposed to address this problem (Ma et al., 2008). Recently variable rate precision irrigation has been investigated. Al-Kufaishi et al. (2006) assessed the feasibility of applying spatially variable irrigation under a center pivot system and found that the loss of water was higher for the uniform application scenarios than that for the VRA scenarios for applications of 20 and 30 mm. Under precision irrigation, water and associated solute movement are designed to vary spatially within the root zone and salt accumulation or leaching of nutrients that influence water balance in the root zone (Mmolawa and Or, 2000; Raine et al., 2007). Many current irrigation systems are open and have relatively low efficiencies of water application (Hagin and Lowengart, 1995, 1999). In addition, water quality relative to management practices has been largely ignored.

15.9.5 Modeling as a Tool for Improving Water Use Efficiency

Since the 1980s, crop production decision support models have been advocated. Models, particularly mechanistic models that strive to simulate water and nutrient transport, and DM production as a function of management and climatic factors are becoming beneficial. Through continued research today there are several models that can be used in decision making regarding water use in specific environments and cropping systems. For example, the AquaCrop model developed by FAO was found to be a good predictor of crop productivity, water requirement, and WUE under water-limiting conditions for maize in different environments (Heng et al., 2009). The SORKAM model predicted an increase in sorghum WUE in the southern High Plains of Texas when a later maturing sorghum cultivar was planted in mid-May at irrigation levels of 3.75 and 5.0 mm day⁻¹ (Baumhardt et al., 2007).

15.9.6 Nutrient and Water Interactions

It is well documented that WUE cannot be achieved without addressing fertility constraints. WUE has been constrained by the supply of both N and P. Selles et al. (1992) suggested that soil testing laboratories should modify their fertilizer

recommendations according to different levels of available water, rather than the traditional dry, normal, and wet classes used. Halvorson et al. (2004) demonstrated that precipitation use efficiency of winter wheat increased with N rate reaching peak after 56 kg N ha⁻¹. Optimal leaf N concentration promoted higher WUE (Heitholt et al., 1991), and low leaf N led to poor WUE in N limited and drought stressed wheat in the southern Great Plains. NUE and WUE were improved when nutrients were placed beneath the surface of the soil at a depth of 15 cm in turfgrass (Murphy and Zaurov, 1994). Inefficient water use can result if N fertilizer is applied during the vegetative phase since it increases transpiration loss by reducing the soluble carbohydrate reserves available for translocation to grain (Angus and van Herwaarden, 2001).

Likewise, increasing soil P availability resulted in increased water use in both water-stressed and non-water-stressed conditions (Payne et al., 1992; Brück et al., 2000). Another study showed that N and P fertilization was related to WUE (Payne et al., 1995). Generally, in non-water-limiting conditions, WUE was improved with higher rates of both nutrients.

15.10 Conclusions

Nutrient and WUE have a lot to do with energy production and use in agriculture. Improving both NUE and WUE can contribute to efficient and productive agricultural system. Improving NUE requires the use of best management practices in a sustainable way and managing both spatial and temporal variability. There is no single factor that can serve as a silver bullet to improve NUE. Variable rate nutrient management systems, foliar fertilization, and biotechnology are some of the new best management practices (BMPs) that may result in huge improvement in N and other NUE in crops. WUE like NUE will always play a pivotal role in agricultural production. But unlike NUE, WUE, especially in dryland environments is a function of temporal or climatic variability. In the vast majority of rainfed production environments, weather changes dramatically from year to year. As a result, WUE changes from year to year and in these environments it is highly unpredictable. Thus, management systems that can buffer or dampen the effects or impact of water play an increasingly important role.

Nutrients interact during numerous biological, physical, or chemical processes along the soil-root-shoot continuum such that the level of one nutrient alters the availability, uptake, or plant response to another nutrient (Zhang et al., 2006). Given the very nature of ionic balance in plant nutrition and the ionic interactions in soil chemistry and fertility, virtually all soil-plant processes involve nutrient interactions, making a comprehensive review a boundless task. This review will focus on key concepts and provide examples to illustrate them. The availability and flow of any given nutrient through the continuum are constantly influenced by the activity and form of other nutrients, and the nature and rate of these interactions are sufficiently complex that they are sometimes beyond our current ability to measure and quantify their impacts. The nutrient interactions that are most often recognized and documented have for the most part been observed in soil fertility experiments that characterize crop nutrient uptake and growth response to one or more nutrients added to the system. Thus, this review will focus on the examples of nutrient and other elemental (e.g., heavy metals) interactions documented in the soil fertility literature, with subsequent discussion of plausible chemical and biological mechanisms of those same interactions along the soil-root-shoot continuum as described in the soil chemistry, soil microbiology, and plant nutrition literature.

Nutrient interactions will be delineated as to their specificity, specific or primary interactions being those in which two nutrients directly react in a chemical or biological process. Nonspecific or secondary nutrient interactions occur when the uptake of one nutrient is indirectly affected by the activity of another nutrient through a series of intermediate plant processes.

16.1 Historical Perspective

Our modern concepts of plant nutrient essentiality and their interactions coevolved with the development of modern chemical principles, as described in reviews by Browne (1944), Ihde (1964), Tisdale et al. (1985), Wild (1988), Black (1993), and Epstein and Bloom (2005). The Law of the Minimum (LM), popularized by Justus von Liebig in the mid-nineteenth century but first succinctly stated by Carl Sprengel, recognized a basic fundamental nature of interactions among these essential nutrients. Sprengel conducted experiments on mineral salts extracted from organic matter and soils and published a list of mineral elements essential for plant growth (van der Ploeg et al., 1999). Furthermore, he wrote in 1828 "...when a plant needs 12 substances to develop, it will not grow if any one of these is missing, and it will grow poorly, when one of these is not available in a sufficiently large amount as required by the nature of the plant."

Liebig subsequently stated in 1855 as part of his LM that "by the deficiency or absence of one necessary constituent, all the others being present, the soil is rendered barren for all crops to the life of which that constituent is indispensible" (Wild, 1988). These pioneers of plant nutrition research established a basic concept of nutrient codependence.

The LM and the concept of plant response to a most limiting nutrient was later modeled by Mitscherlich when he published his "Law of Diminishing Returns" (Mitscherlich, 1909). The model depicts a plant yield (y) exponential response to increasing nutrient availability from fertilizer and soil (x + b) that rises to a plateau (the shape of the rise defined by constant [c] as it nears a maximum potential yield [A]). As Black (1993) summarized, while many other empirical polynomial models have been used to represent yield response to nutrient availability, the

Mitscherlich model is unique in that the variables represent biological concepts. The nonfertilizer soil nutrient supply (b), the nutrient use efficiency represented by the rise to the maximum (c), and the maximum yield (A) are all influenced by the status of other growth factors, including other essential nutrients (Figure 16.1).

Comparative analysis of two-way nutrient responses provides insight into the nature of interactions between those nutrients. Historically, there has been considerable debate whether "c" is constant for a given species response to a specific nutrient (N1). Mitscherlich contended that "c" was in fact inherently constant, but van der Pauw (1952) statistically reanalyzed Mitscherlich's data and found a sizable variation in "c" values. Furthermore, subsequent experiments provide compelling evidence and argument for variable "c" values for a given nutrient, notably when a second nutrient (N2) interacts to change the true plant availability of the nutrient N1 or N2 competes with N1 for uptake (see Black, 1993). In retrospect, these two possibilities of having constant or variable "c" need not be mutually exclusive. It is plausible that the alteration of factors "c," "A," or both depends on the nature of the interaction between growth factors and whether they are primary or secondary in the nature.

For the purpose of this review, primary nutrient interactions are defined as specific chemical and biochemical interactions between two nutrients occurring in the bulk soil, soil solution, rhizosphere, or root cell surface that affects the activity,

bioavailability, or ion transport of one or both nutrients. In contrast, secondary nutrient interactions are defined as non-specific nutrient interactions mediated by general physiological responses such as compensatory root growth (Drew and Saker, 1975) to one nutrient that indirectly influence the uptake and assimilation of a second nutrient. Examples of primary and secondary nutrient interactions are listed in Table 16.1.

The constancy or variability of "A" is dependent on whether the second nutrient N2 is supplied in limiting or nonlimiting levels. Obviously, if N2 is nonyield limiting at all levels, then maximum yield "A" will remain unaffected by variation in N2. The constancy or variability of "c" is dependent on the specific or nonspecific nutrient interactions that can alter the nutrient use efficiency of N1. For example, changes in "c" in response to the level of N2 may reflect specific primary chemical interactions affecting nutrient activities that represent their immediate bioavailability as reflected by the ionic activity of the absorbed nutrient form, and how changes would affect nutrient uptake and utilization. Nonspecific secondary interactions, mediated through indirect effects on general plant growth, root, or rhizosphere bacterial activities, might also alter "c" by changing the plant's overall demand for N1 or by changing the N1 nutrient uptake or utilization efficiency. Four hypothetical scenarios, portrayed in Figure 16.1 with modeled yield responses to nutrient 1 (N1) as affected by nutrient 2 (N2) levels, are represented by Mitscherlich equations.

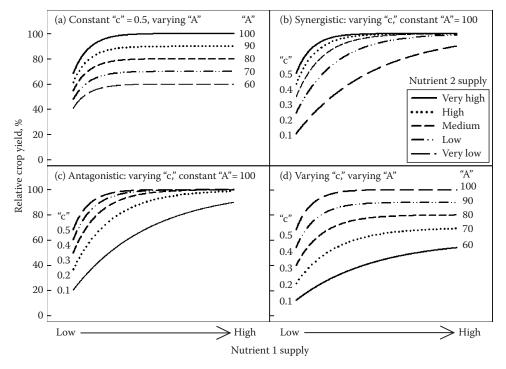

FIGURE 16.1 Depiction of four interaction scenarios between two nutrients (1 and 2) as modeled with the Mitscherlich equation. The legend in Panel (b) indicates level of nutrient 2 supply for all panels. Values for "A" and "c" for each level of nutrient 2 are included in each panel where appropriate. Panel (a): The classic "Mitscherlich" response depicting proportional yield increases in response to incremental levels of nutrients 1 and 2. Panel (b): Increasing levels of nutrient 2 increase the utilization efficiency of nutrient 1 (synergistic). Panel (c): Increasing levels of nutrient 2 decrease the utilization efficiency of nutrient 1 (antagonistic). Panel d: The classic "Law of the Minimum" response, where nutrient 1 is initially most limiting thus nutrient 2 has no effect on crop yield; but with increasing levels of nutrient 1, nutrient 2 has increasing impact on crop yield.

TABLE 16.1 Examples of Primary (Specific) and Secondary (Nonspecific) Nutrient Interactions

* *	
Primary	Secondary
Cation-anion exchange	Increased yield potential and nutrient demand
Cation-anion precipitation	Altered nutrient uptake or utilization efficiency
Ion pairing	Modification of rhizosphere chemistry, biology
Ion uptake synergism or antagonism	Modification of soil solution ionic strength

Scenario 1 (Figure 16.1a) depicts Mitscherlich's concept of variable "A" and constant "c." This scenario occurs when N1 and N2 are both initially present at yield-limiting levels, responding simultaneously to incremental increases in both nutrients. Since N2 does not affect N1 bioavailability or uptake and utilization efficiencies, the shape of the rise ("c") to "A" is unaffected. This type of response is referred to as the "Mitscherlich (MTS) response" (Zhang et al., 2007).

Scenario 2 (Figure 16.1b) depicts a specific interaction affecting "c" but not "A" in which N2 levels specifically (e.g., ion uptake synergism) or nonspecifically (e.g., increased root proliferation) increase "c" by improving the N1 uptake or utilization efficiency, while "A" remains unchanged.

Scenario 3 (Figure 16.1c) represents the opposite situation of scenario 2, whereby an increased level of nutrient N2 inhibits the uptake of nutrient N1 due to specific ion antagonism at the N1 influx porter or due to specific or nonspecific reduction in N1 bioavailability. Nutrient 2 is present in nonyield limiting supply, so there is no change in "A," but more N1 supply is required to reach "A" due to the antagonism of N2, which reduces the N1 nutrient use efficiency and shifts "c" to a lower value.

Scenario 4 (Figure 16.1d) depicts situations in which both N1 and N2 are initially limiting, but if N1 is the most limiting nutrient, then the crop will primarily respond to N1 until it reaches a level in which it is no longer the most limiting nutrient and then the crop will respond to increases in N2. The "A" increases with N2 levels, but "c" values decrease. This represents the spirit of Liebig's LM, and has thus been referred to as the LM type response (Zhang et al., 2007) or the Liebig response.

Interactions amongst growth promoting factors were described by Bloom et al. (1985), in the context of a "Multiple Limitation Hypothesis (MLH)," to occur in resource allocation terms, whereby plants invest resources into homeostatic mechanisms for acquiring the most growth limiting resources it needs, at the expense of acquiring less limiting resources. Zhang et al. (2007) applied MLH to nutrient interactions by surmising that a response to a nutrient should increase with increased availability of other nutrients, similar to the MTS response, provided they are not toxic. Rubio et al. (2003) examined 60 responses of *Lemna minor* to combinations of N, P, K, and Mg, and found 23 LM responses, 17 MLH responses, and 20 undefined responses. Type of response was highly dependent on the nutrient pairings. In contrast, Wood et al. (1972) examined 69 experiments and found

that 49 matched the LM response and only eight were classified as MTS. These researchers assumed that either of the two theories—MLH or MTS—(Figure 16.1a) or LM (Figure 16.1d) would represent the nature of all nutrient responses and nutrient interactions. However, in both studies there were undefined responses that could not be characterized by either theory. In retrospect, these undefined responses could be rationalized with scenarios 2 (Figure 16.1b) or 3 (Figure 16.1c) in which N1 use efficiencies are altered by specific or nonspecific nutrient interactions.

16.2 Conceptual and Quantitative Frameworks of Nutrient Interaction Mechanisms

Fried and Broeshart (1967) published a conceptual framework depicting nutrient flow through the soil solid-soil solution-root-shoot continuum. They contended root uptake would be the rate-limiting step at equilibrium, a supposition soon after contested (Nye, 1977) and largely disproven with numerous subsequent experiments (see Barber, 1995; Silberbush, 1996) demonstrating that nutrient delivery from and through the soil to the plant root is often rate limiting for sparingly soluble nutrients. A corollary to that concept would be that nutrient interactions affecting availability and mobility are most often important for relatively immobile nutrients such as P and K, whereas nutrient interactions affecting the root uptake and utilization processes are most often important for mobile nutrients such as Ca and NO₃-N.

The essential contribution of the Fried-Broeshart model was that it provided the conceptual basis for subsequent quantitative soil-nutrient uptake models (Baldwin and Nye, 1974; Claassen and Barber, 1976; Rengel, 1993; Barber, 1995; Silberbush, 1996; Claassen and Steingrobe, 1999; Hopmans and Bristow, 2002). These models attempt to simulate soil processes affecting nutrient solubility and movement to plant roots, integrated with simulations of root growth and nutrient uptake. For the sake of simplicity, most models are single nutrient based and have not included modules to account for the multitude of nutrient interactions that can occur along the continuum. Exceptions include a multi-ion uptake model published by Bouldin (1989) that stresses the importance of maintenance of electrical neutrality through balanced cation-anion movement through the system. Relative ratios of cations [K/(Ca + Mg)] on exchange sites and in solution were incorporated into the model. Koenig and Pan (1996b) demonstrated how single ion nutrient uptake models can be used to assess potential effects of soil nutrient interactions on crop nutrient uptake, by modeling cation exchange-driven shifts of quantity/intensity (Q/I) relationships that affect the bioavailability of the absorbed nutrient. Calcium exchange for NH₄ increases solution NH₄ concentrations, a limiting factor in NH₄ diffusion rates to and into plant roots (Table 16.2). This proposed mechanism for Ca-stimulated NH₄ uptake was suggested as an alternative hypothesis to prior theories on membrane level Ca-NH₄ synergies (Fenn et al., 1987; Fenn and Taylor, 1990).

TABLE 16.2 Soil Supply Parameters Used in the Simulation of NH_4 Uptake and Predicted NH_4 Uptake over a 10 d Period for Rice (*Oryza sativa* L.) and Corn (*Zea mays* L.) as Influenced by Ca

					10 Day N	N Uptake
	C_s	C_1	В	D _e	Rice	Corn
Condition	$mg\;N\;kg^{-1}$	$mg\;N\;L^{-1}$	$L kg^{-1}$	$cm^2 s^{-1}$	mş	g N
-Ca	100	12	5.44	2.10×10^{-7}	415	27
+Ca	100	32	1.79	6.39×10^{-7}	506	29

16.2.1 Nutrient Interactions at the Soil Solid-Solution Interface

Primary nutrient interactions occur at the different stages of the soil–plant continuum (Table 16.1), generally related to cation–cation, anion–anion, or cation–anion chemical interactions.

Chemical and biological interactions affecting nutrient equilibria and flow rates between the labile fraction of the soil solid and solution phases influence solution ionic activities and transport to plant roots (Degryse et al., 2009). Cation availability is reduced by adsorption to negatively charged organic matter, oxides, and clay minerals. Precipitation with reactive anions also reduces soluble cation availability. Sorption into the labile pool occurs within hours following addition, whereas slower "fixation" reactions reduce the labile pool. Fixation of K and NH₄ into interlayers of 2:1 layer silicates or "fixation" of metal cations during diffusion into hydroxides or precipitates, ion adsorption, and biological immobilization all remove nutrients from the soil solution, potentially reducing their immediate availability to the plant root. Conversely, depending on the reversibility of these reactions and the solubility of the compounds, those nutrients are held in reserve, preventing nutrient leaching. Upon depletion from the soil solution or with a shift in chemistry or biology affecting the equilibria, these nutrients can be solubilized later in the growing season. For example, the availability of soluble anions promotes cation desorption, solubility, and mobility (Sakuri and Huang, 1996).

The importance of ion composition of the soil solution including cationic micronutrients (McGeorge, 1924), elemental toxicities (Magistad, 1925), and P forms (Pierre and Parker, 1927) as a critical factor in plant response to soil conditions has been recognized for more than a century (Adams, 1974; Sparks, 1984). Solid phase–solution phase solubility, as affected by solubility products of salts and by ion exchange reactions were first characterized with solubility diagrams proposed by Aslyng (1954). Ion activities, as affected by nutrient interactions, were calculated according to the Debye–Huckel equation and related to root growth (Howard and Adams, 1965, Adams, 1966; Adams and Lund, 1966). Subsequently, recognition of nutrient interactions of ion pair formation refined estimates of ion activities (Bennett and Adams, 1970). Tedious iterative calculations of specific ion activities were automated in computer programs such

as GEOCHEM (Sposito and Mattigod, 1980) and MINTEQ (Brown and Allison, 1987) despite the fact that these activities are as Sposito (1984) characterized, an immeasurable "thermodynamic illusion." Nevertheless, these models promoted more extensive research that demonstrated correlations between specific ion activities in soil solutions with root growth and ion uptake (Hough et al., 2005). Nutrient interactions in soil solutions that can affect specific ion activities are thereby manifested in this model by either contributing to or interfering with (1) the formation of insoluble precipitates or sorption of ion pairs (e.g., Bolan et al., 1993; Pearce and Sumner, 1997), (2) the formation of soluble ion pairs (e.g., Kinraide and Parker, 1987), or (3) a buildup of ionic strength, which inversely affects ion activities (e.g., Kalis et al., 2008).

16.2.2 Specific Nutrient Interactions at the Solution–Root Interface

Primary and secondary nutrient interactions in the rhizosphere involve both chemical and biological processes. The ion uptake models described above assume ion uptake by plant roots is related to ion concentration or ion activity in the soil solution of the rhizosphere. Thus, primary nutrient interactions in the rhizosphere affecting ion activities would affect plant uptake and plant response. Root metabolism resulting in differential depletion or accumulation of nutrients in the rhizosphere, rhizosphere pH modification, and root release of complexing organic compounds all potentially change the rhizosphere chemistry affecting ion activities (Marschner, 1995; Hinsinger, 1998). In addition, secondary nutrient effects on rhizosphere microbial activities also influence the forms, activities, and uptake of other nutrients.

Much of our knowledge of nutrient interactions at the root surface affecting ion uptake has been derived from solution-grown plants with varied nutrient compositions (Reid, 1999; Epstein and Bloom, 2005). Not coincidentally, ion uptake response to increasing ion activity in the rooting solution resembles crop response to increasing nutrient supply in the field. The diminishing rise to a maximum characterized by the MTS equation is reflective of similarly shaped ion uptake responses to nutrient supply at the root surface, typically characterized by single or multi-phased Michaelis-Menten kinetics. Likewise, some field level nutrient interactions have similar patterns of antagonism or synergism of ion uptake at cellular or root levels (see Epstein and Bloom, 2005). These interactions are expressed in changes in the shape of the rise to maximum, defined by K_m, and/or in changes in V_{max} (Wang et al., 1993). Like-charged ions tend to be antagonistic, while mobile counter-ions can facilitate greater uptake.

Molecular ion transport mechanisms of major nutrients have recently been reviewed (Miller et al., 2009). Families of membrane-bound protein transporters of N, P, and S have been identified, classified, and mapped to gene sequences. Plant regulation and control mechanisms of ion transporters coordinate relative uptake rates among nutrients to maintain internal nutrient balance during shifting nutrient availability regimes (Hesse et al., 2004).

16.2.3 Cation-Cation Interactions

Cation interactions that influence ion uptake rates occur at each stage of the soil–plant continuum. Cation exchange interactions with negatively charged clay and organic matter affect quantities held in reserve, solution cation activities (intensity), and flux rates to plant roots. The Q/I ratio is a measure of this relationship between solid and solution phase, and is a key parameter (buffer power, "b") of soil nutrient uptake models (Barber, 1995; Claassen and Steingrobe, 1999). The Barber and Cushman (1981) model predicted that when the total concentration of a cation in soil is held constant and buffer capacity is reduced in the presence of other exchangeable cations, then the cationic activity in solution increases, which, in turn, can drive an increase in cation uptake rates.

Cation exchange also occurs at the root surface on negative sites residing in the cell wall and plasmalemma. Inflow of cations through the root apoplasm by diffusion or mass flow is influenced by exchange properties of carboxylic groups of cell wall structural components such as polygalacturonic acid (Marschner, 1995). These exchange sites harbor a reserve pool of cations for membrane transport (Epstein and Leggett, 1954). Root cation exchange capacity (CEC) differs among species, and dicotyledonous plants are generally higher in exchange capacity than monocotyledonous plants. As in soils, selective binding of multivalent cations over monovalent cations occurs at the cell wall surface, increasing the concentration of divalent and trivalent cations in the apoplasm of species with high root CEC. The importance of this exchange phenomenon is inferred from correlations between root CEC and cation uptake selectivity differences among plant species (Crooke and Knight, 1962; Haynes, 1980). Conceptually, the cation selectivity on the root exchange sites influence the ratio of cations at the sites of membrane transport. Reid (1999) cautioned that research focused on cell wall electrostatic properties may have overshadowed more important charge properties of the plasmalemma. He argues that the membrane charge is more important due to proximity to the transport sites. Optimal calcium effects of increasing apparent K_m of Rb uptake by yeast cells (Gage et al., 1985) was offered as evidence for this influence of interacting cations on membrane adsorption and absorption. These electrostatic binding interactions in the cell wall and plasma membrane are thought to play an important role in trace element uptake and toxicity as well (Yermiyahu and Kinraide, 2005).

Calcium has long been recognized for its special synergistic role in facilitating ion uptake (Viets, 1944), which is commonly attributed to its positive maintenance of membrane integrity and subsequent membrane transport selectivity of other ions (Marschner, 1995; Epstein and Bloom, 2005). Membrane stabilization is achieved by calcium bridging of carboxylate and phosphate groups of the membrane phospholipids (Caldwell and Haug, 1981). Zinc nutrition has also been linked to membrane integrity and ion retention by roots (Welch et al., 1999). Ca and Mg can reduce the phytotoxicity of Cu, Zn, Al, Na, and H by reducing the electrostatic attraction of the root plasma membrane for these cations (Kinraide et al., 2004).

Commonly, a deficiency in one cationic nutrient will increase the uptake of other cations of similar properties. Direct interference of one cation on the porter-binding of a substrate cation has long been offered as a principle mechanism of cation antagonistic competition between like-charged cations (Epstein, 1972). Aluminum toxicity can be manifested as a primary mechanism of competitive inhibition of divalent cation uptake (Rengel and Robinson, 1989; Rengel, 1990) or secondary effects on root growth and general reduction of nutrient absorptive capacity (Foy, 1988). Primary interference of Al on Mg uptake is rapid (Rengel, 1990) and these types of cation interactions may also be attributed to altered surface charge potential of the cell wall (Gage et al., 1985). Antagonistic interactions among K/Na (Mohammadi et al., 2008; Luan et al., 2009), may relate to both transporter activity and synthesis (Yao et al., 2010). In the field, low K can result in increased Na uptake (Yoshida and Castenada, 1969). Antagonism between NH₄/K is also well recognized during the seedling (Vale et al., 1987; Hoopen et al., 2010) and reproductive (Pan et al., 1986) stages of cereal crops, with this interaction also involving a competition between the two cations for porter sites (Hoopen et al., 2010).

Cation-cation interactions also occur during internal plant transport and mobilization processes (Morgan and Jackson, 1976). For example, excess K is well known to suppress forage Mg accumulation, due to altered Mg translocation from root to shoot (Ohno and Grunes, 1985). Welch et al. (1999) demonstrated that Zn sufficient wheat had lower phloem movement of Cd to the grain compared to Zn deficient plants. Similar observations were made of Zn influences on Mn movement in root phloem (Pearson and Rengel, 1995).

Cation-cation antagonism in micronutrient and heavy metal uptake is also well documented. Calcium-inhibited Zn uptake and translocation was noted in wheat (Hart et al., 1998). Cadmium uptake can be increased (Girling and Peterson, 1981) or decreased (Honma and Hirata, 1978; Cataldo et al., 1983; Keltjens and van Beuschichem, 1998) by the addition of other metals depending on the resulting ratios of Cd and competing metals in solution. Rice accumulated more Fe and Mn under Zn deficient conditions (Sajwan and Lindsay, 1986), and Mn uptake by this crop has also been correlated to Mn/Fe activity ratios, suggesting an antagonism between Mn and Fe (Moore and Patrick, 1989). Excess Cu-induced Fe deficiency in wheat (Aurelia et al., 2008). Zinc deficiency stimulated root exudation and enhanced mobilization of both Zn and Cu that might stimulate cationic micronutrient uptake (Degryse et al., 2008).

16.2.4 Cation-Anion Interactions

Nutrient interactions between cations and anions may either increase or decrease nutrient use efficiency, depending on the dominance of reactions affecting their bioavailability in precipitation/adsorption/dissolution and ion pairing reactions relative to their role in providing ionic balance during uptake and translocation of those nutrients. For example, $NH_4/metal$ interactions depend on opposing reactions at the

solid–solution interface versus the solution–root interface. In solution culture experiments, $\mathrm{NH_4}$ antagonizes heavy metal uptake (Chaudhry and Loneragan, 1972) due to cation binding interference in the plasma membrane. In contrast, soil experiments demonstrated that the mobility of the chloride $\mathrm{NH_4}$ salt had the greatest positive influence on increasing Cd absorption by plants compared to less soluble anions, $\mathrm{SO_4}$ and $\mathrm{PO_4}$ (Bingham et al., 1983, 1984; Ohtani et al., 2007), overshadowing possible effects of cation–cation antagonism. The presence of chloride optimized the response to enhanced $\mathrm{NH_4}$ supply in wheat, either by helping to facilitate transport to, or into the root (Koenig and Pan, 1996a). In contrast, cation composition of soils influences phosphate solubility and precipitation, whereby Ca promotes P precipitation while Na increases solution P (Curtin and Syers, 2001).

The formation of soluble ion pairs increases total nutrient concentration in the soil solution, potentially facilitating greater nutrient transport to root surfaces, but at the same time, may affect the activity of charged species that directly interact with roots. For example, the formation of soluble ${\rm AlSO_4^+}$ was proposed by Kinraide and Parker (1987) to decrease Al toxicity in wheat due to decreased ${\rm Al^{3+}}$ activity.

At the root surface, the presence of soluble anions can increase cation uptake. For example, Ca uptake by corn roots in solution was greater from NO_3 and Cl salts compared to SO_4 (Maas, 1969).

High P-induced Zn deficiency is often cited in the literature as an important anion–cation antagonism (Jones, 1991), but direct evidence of this type of interaction is sparse (Hernandez and Killorn, 2009) and Zn responses on high P soils have not shown Zn deficiencies (Mallarino and Webb, 1995).

16.2.5 Anion-Anion Interactions

Similar to cation–cation interactions, anions interact at the soil surface as well as the root cell surface to affect anion uptake by plants. Anion concentrations in soil solution influence anion adsorption of variable charged clays (Roy et al., 1986; Manning and Goldberg, 1996) whereby competing anions may increase soil solution anionic concentrations and increase plant uptake. For example, the addition of CO₃ and SO₄ salts to calcareous soil increased PO₄ availability and movement (Olatuyi et al., 2009).

In addition, anions can interact by competing at anion membrane channels that facilitate uptake (White and Broadley, 2001). Leggett and Epstein (1956) demonstrated that Se interferes with SO₄ influx while other anions have no effect. Anion antagonism is best exemplified by mutual antagonisms between Cl and NO₃. High Cl supply inhibits NO₃ uptake and high NO₃ reduces Cl uptake (Mengel and Kirkby, 1987). Interactions vary at high and low affinity porter sites in the root cell membrane (Siddiqi et al., 1990). Inhibition of N uptake by NaCl is often attributed to the role of Cl in antagonizing NO₃ absorption in a scenario 3 type response (Figure 16.2; Massa et al., 2009).

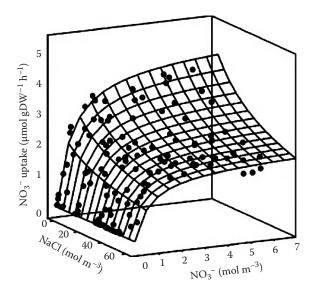

FIGURE 16.2 NaCl and NO₃ effects on NO₃ uptake in *Rosa*. (With kind permission from Springer Science+Business Media: Massa, D., N.S. Mattson, and H.J. Lieth. 2009. Effects of saline root environment (NaCl) on nitrate and potassium uptake kinetics for rose plants: A Michaelis-Menten modeling approach. Plant Soil 318:101–115.)

16.2.6 Secondary, Nonspecific Nutrient Interactions

Nutrients can have secondary effects on the uptake of other nutrients through their alteration of microbial activities in the rhizosphere, plant root activity, and rhizosphere chemical or biochemical modification (Marschner et al., 1987). In contrast to specific nutrient interactions, the uptake of multiple nutrients is affected by these secondary interactions. Furthermore, interactions between any of the macronutrients that have major influence on plant growth and development will include secondary effects on sink demand for other nutrients and/or via increased root proliferation and nutrient absorption capacity (Forde and Lorenzo, 2001; Williamson et al., 2001). Classic nonspecific nutrient interactions include N interactions with other nutrients, when the level of N bioavailability influences growth, yield potential, and corresponding demand for other nutrients.

An example of microbially mediated secondary nutrient interactions involves P-deficiency enhanced wheat responses to arbuscular mycorrhizal fungal inoculation, which increases Zn and Cu uptake and accumulation due to increased sorptive area, but not Fe and Mn (Mohammad et al., 1995). Kothari et al. (1991) suggested that the mycorrhizae decrease the potential for Mn reduction in the rhizosphere by lowering the number of Mn reducing bacteria. Furthermore, Zn binds to polyphosphates, a major P transport form in mycorrhizal hyphae, adding a primary nutrient interaction to this complex system.

Another prominent example of a nonspecific interaction is the rhizosphere acidification of plant roots in response to a nutrient deficiency, which, in turn, affects the solubility and bioavailability of pH-sensitive nutrients such as P and the cationic micronutrients (Marschner et al., 1987). Nitrogen form during N_2 fixation

or NH₄ and NO₃ uptake by plants has the largest impact on cation-anion balance of absorbed charge, which is counterbalanced by net efflux of H+ during excess cation uptake or OH- equivalents during excess anion uptake (Riley and Barber, 1971; Israel and Jackson, 1982). More recently, rhizosphere acidification has been observed to be a light-mediated reaction, seemingly tightly coupled to photosynthesis and energy transport to roots (Rao et al., 2002). Acidification of the rhizosphere then has secondary effects on nutrient availability and determines the propensity of certain species to utilize sparingly soluble Ca-phosphates (Shen et al., 2004; Zhou et al., 2009) and cationic micronutrients (Tills and Alloway, 1981). Manganese-deficient grass species are predisposed to take-all disease caused by Gaeumannomyces graminis var. tritici (Graham and Rovira, 1984), and NH4 nutrition-induced acidification and reduction of Mn to the plantavailable Mn²⁺ form improves Mn nutrition and reduces disease incidence (Brennan, 1992; Heckman et al., 2003).

Secondary micronutrient interactions can be utilized agronomically to enhance micronutrient uptake. Recent efforts to biofortify food crops with enhanced micronutrients place greater importance in recognizing mechanisms influencing micronutrient uptake, accumulation, and balance in designing agronomic systems (Zhang, 2009). Several researchers have recognized the benefits of intercropping Graminaceae and dicotyledonous crops in improving Zn and Cu accumulation in the dicot plant. This has been demonstrated in wheat/chickpea and lentil (Gunes et al., 2007) and maize/peanut (Zao et al., 2000). It is proposed that the Graminaceae crop, using strategy I in producing phytosiderophores under Fe deficiency to solubilize and acquire Fe and Zn in the comingled rhizosphere of both plant species, thereby enhances the cationic micronutrient uptake of both plants. The supply of FePO4 was shown to increase Ca and Zn uptake in wheat, possibly due to a rhizosphere acidification response (Li et al., 2004).

Nitrogen and S fertility synergistically interact to affect crop grain yield (Wang et al., 1976; Randall et al., 1981), grain protein

and grain quality (Randall et al., 1990), N utilization efficiency (Mahli and Gill, 2002), and N use efficiency (Salvagiotti and Miralles, 2008). Optimization of S nutrition increases N use efficiency, mainly by increasing N uptake efficiency in grass species (Brown et al., 2000; Figure 16.3, Salvagiotti et al., 2009). These responses align with scenario 1 (see Figure 16.1a).

In Brassica crops, yield and oil content (Ahmad et al., 1999), glucosinolate (Kim et al., 2002; Schonhof et al., 2007), and isothiocyanate (Gerendas et al., 2008) concentrations are influenced by relative supplies of N and S. Moderate N and S availability optimized production of benzyl-isothiocyanate in cress (Gerendas et al., 2008). In contrast to the previously cited improved nutrient use efficiency responses of grass species, Jackson (2000) observed a Liebig-type N × S interactive response in canola (scenario 4, see Figure 16.1d), in which N was initially more limiting than S, and yield response to S was apparent only at higher N supply (Figure 16.4b). In soil in which S availability was lower (Figure 16.4a), added S increased yield potential, which in turn increased N demand and the N supply required to obtain "A."

The field observations of N and S fertility interactions are well reflected at the cellular and root levels (Reuveny et al., 1980; Hesse et al., 2004). Mineral nutritional studies have revealed the uptake and assimilation of N and S are coregulated by the substrate ions and their assimilatory products (Clarkson et al., 1989; Koprivova et al., 2000; Hesse et al., 2004). Sulfate uptake and assimilation are regulated by O-acetylserine, a cysteine precursor that is in itself regulated by N availability and assimilation (Koprivova et al., 2000). Excess cysteine production when S is high or N is limiting will repress S uptake and assimilation (Zhao et al., 1999). Conversely, N uptake and assimilation is depressed during S starvation (Clarkson et al., 1989; Prosser et al., 2001) as arginine and asparagine accumulate with reduced cysteine and methionine production (Thomas et al., 2000; Prosser et al., 2001).

Nonspecific N–P interactions are commonly observed if for no other reason that they are typically the two most limiting nutrients in crop production and therefore demonstrate additive

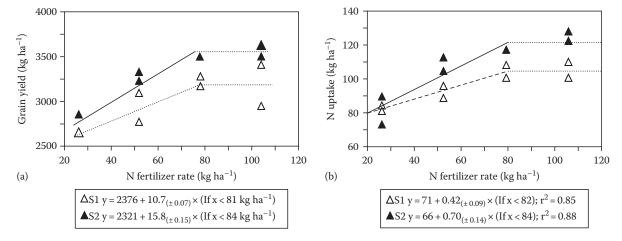

FIGURE 16.3 Wheat (a) grain yield and (b) N uptake responses to N fertilizer rate at two S levels. (From Salvagiotti, F., J.H.M. Castellarín, D.J. Miralles, and H.M. Pedrol. 2009. Sulfur fertilization improves nitrogen use efficiency in wheat by increasing nitrogen uptake. Field Crops Res. 113:170–177. Copyright (2009), with permission from Elsevier.)

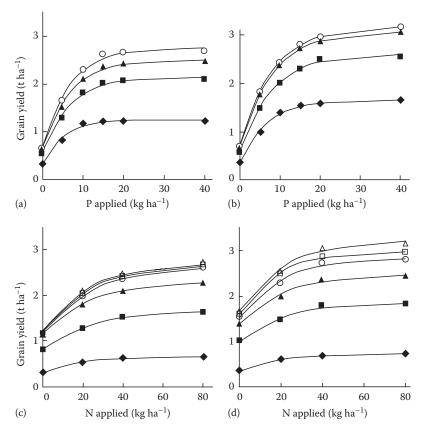

FIGURE 16.5 Canola (a, c) and wheat (b, d) responses to fertilizer P at increasing levels of N (a, b) and to fertilizer N at increasing levels of P (c, d). Nitrogen rates for panels (a) and (b) were 0 (\spadesuit), 20 (\blacksquare), 40 (\blacktriangle), and 80 (\spadesuit) kg ha⁻¹. Phosphorus rates for panels (c) and (d) were 0 (\spadesuit), 5 (\blacksquare), 10 (\blacktriangle), 15 (\bigcirc), 20 (\square), and 40 (\triangle) kg P ha⁻¹. (From Brennan, R.F., and M.D.A. Bolland. 2009. Comparing the nitrogen and phosphorus requirements of canola and wheat for grain yield and quality. Crop Pasture Sci. 60:566–577. With permission from CSIRO Publishing, http://www.publish.csiro.au/nid/40/paper/CP08401.htm)

or synergistic yield effects in bringing both nutrients to sufficient levels of availability. Mechanisms of N-P interactions have been ascribed to all stages of the soil-plant continuum (Miller, 1974). Brennan and Bolland (2009) demonstrated classic Liebigtype responses (see Figure 16.1d) to P at varying levels of N (Figure 16.5a and b) suggesting P was more critically limiting than N in these soils. Nitrogen level did not substantially alter the optimal level of P. The same data plotted differently exhibited an MTS-type response (see Figure 16.1a) to N at varying levels of P in canola and wheat (Figure 16.5c and d), suggesting there were limited specific interactions between the two nutrients that affected their bioavailability and that P availability was at least as critically limiting as N, such that optimization of P increased the N supply required to obtain "A." However, in other instances, a Liebig-type response (see Figure 16.1d) to N and P is observed (Nuttall et al., 1992) in which the level of N increased the optimal level of P supply.

16.3 Conclusions

Nutrient interactions are important factors to consider in accurately predicting nutrient responses in soil fertility management. Both primary and secondary interactions will influence nutrient use, uptake, and utilization efficiencies. Interactions occur at all points along the soil-plant continuum, and multinutrient quantitative models are needed to assess the relative importance and influence of individual interactions that are at times in synchrony and sometimes counter-opposing. Full recognition of the nature of these interactions will better allow us to understand the nature of variable yield responses to nutrient supplies. Shapes of nutrient response curves are influenced by the relative severity of the deficiencies of the interacting nutrients, the specificity with which the nutrients interact in influencing their relative availabilities and ability to react with root membrane surfaces, and their relative ability to influence plant internal processes and overall nutrient demand.

Franklin D. Roosevelt

oil is a dynamic and complex system. Processes in the soil environment are interdependent and interrelated. For a long time, research in soil science has focused mainly on topics along the lines of the traditional disciplines of soil science. This concept led to research efforts that concentrated on well defined, yet limited in number, processes and properties (i.e., studies in soil physics or soil chemistry). However, a comprehensive understanding of the soil environment requires that this approach be accompanied by a more realistic interdisciplinary perspective that considers processes arising from and affected by interactions among properties across these traditional disciplines of soil science.

In light of the above, the current part is devoted to interdisciplinary facets of soil science with special emphasis given to aspects related to soil degradation. Soils are fundamental to the well-being and productivity of both agricultural and natural ecosystems. Hence, the state of soils in various different ecosystems is of concern and has been receiving increased attention globally. The part comprises chapters that discuss, from an interdisciplinary perspective, degradation of soils by salinity (Chapter 17), sodicity (Chapter 18), water repellency (Chapter 19), water logging (Chapter 20), acid sulfate conditions (Chapter 21), water and wind erosion (Chapters 22 and 23), application of wastes (Chapter 24), and tillage (Chapter 25). The final chapter (Chapter 26) discusses the concept of soil quality for agriculture and the environment, and reviews approaches for its evaluation.

I wish to thank all the authors for their valuable contributions and extend my deep appreciation to the reviewers for their invaluable comments and criticism that helped maintain the quality of this part.

R. Keren Agricultural Research Organization

17.1 Origin and Distribution of Saline Soils

The history of agriculture has shown that irrigated agriculture cannot survive in perpetuity without adequate salt balance and drainage. The length of time that irrigated agriculture can survive without adequate drainage depends on hydrogeology and water management. Of the world's cultivated lands, about 831 million hectares are saline (Martinez-Beltran and Manzur, 2005). Salt-affected soils occur in more than 100 countries of the world (Szabolcs, 1989). 67% of the agricultural area has a potential for "transient salinity," a type of non-groundwater-associated salinity (Rengasamy, 2006).

Inland saline waters usually contain $500-30,000\,\mathrm{mg}$ L⁻¹ of dissolved solids (EC $0.7-42\,\mathrm{dS}$ m⁻¹), while ocean water has an average dissolved solid concentration of $33,000\,\mathrm{mg}$ L⁻¹, and the Dead Sea, Israel, $270,000\,\mathrm{mg}$ L⁻¹ (hypersaline). Common sources of saline water for agricultural use are ground or surface waters. The main processes by which soluble salts enter the soil and groundwater include weathering of primary and secondary minerals and application of waters containing salts. The importance of each source depends on the type of soil, climate conditions, and agricultural management.

17.1.1 Mineral Weathering

Salt formation takes place during the process of minerals weathering. The accumulation of these soluble salts in groundwater affects water quality, which depends on the natural salinity of the soil and the geologic materials with which the water has

been in contact. Many soils from arid and semiarid regions and primary minerals such as olivine, hornblende, oligoclase, and others contribute substantial amounts of salts from weathering (Rhoades et al., 1968). In all cases, the total salt content of the displaced soil solutions was higher than that of the irrigation waters being applied.

Water within sedimentary strata become increasingly saline with increasing depth (Craig, 1970) with the sequence being SO_4^{2-} rich water near the surface, HCO_3^- water at an intermediate level, and more concentrated Cl^- solutions at greater depths. This water becomes saline through weathering of primary and secondary minerals.

Predictions of soil mineral weathering and soil solution compositions can be made using stability diagrams (Kittrick, 1977; Lindsay, 1979). Mineral solubility is calculated from appropriate mineral equilibrium constants. Limitations of this approach are (1) the availability of adequate data on the solubilities or free energies of formation of various minerals as well as dissolved species present in soil solution, and (2) the paucity of information on the kinetics of minerals dissolution. Thermodynamic data generally are more accurate for the primary minerals involved in increasing the salinity of the soil solution (Rhoades et al., 1968) than for the secondary minerals (Kittrick, 1977). The major ions in the dissolved mineral salts are Na, Ca, Mg, K, Cl, SO₄, HCO₃, CO₃, and NO₃.

17.1.2 Sea Water Intrusion

In coastal areas, salt water intrusion and submergence of the low-lying lands by sea water cause salinization of groundwater and soils, while surface waters could become saline through tidal fluctuations. As the high tide moves into a coastal area, sea water moves into streams and drainage canals and travels inland. This upstream migration of sea water alters the quality of water in streams and drainage canals significantly.

17.1.3 Deposition of Salts by Rainfall

The composition of atmospheric salt deposition varies with distance from the source. The salt is predominantly NaCl at the coast, and becomes dominated by ${\rm Ca^{2+}}$ and ${\rm SO_4^{2-}}$ inland. Atmospheric contribution to the salt load of arid lands, which is from 10% to 25% of the total yearly contribution from weathering (Bresler et al., 1982), is often overlooked, but is a factor that must be considered in highly weathered landscapes that have poor drainage.

17.1.4 Deposit and Secondary Salinization

Throughout geologic time, sea water has inundated large areas of the continents that have, subsequently, been uplifted and salts deposited when the water evaporated. Salt bodies, which lie beneath the soil surface, formed when inland lakes evaporated (e.g., Searles Lake, CA). These salts were deposited in Pleistocene and Holocene times during major dry episodes. The salts contain varying mixtures of saline minerals such as halite, trona, and nahcolite (Smith, 1979). The term fossil salt has been used to describe the salinity of these deposits, which are substantial sources of salinity.

Irrigation with poor quality water, inadequate leaching, seepage from canals, high water tables, and high evaporation rates all contribute to secondary salinization of irrigated soils. These salts will reduce crop yield if they accumulate in the root zone.

The development of waterlogged soils is mainly associated with low-lying lands having poor physical condition and internal drainage. These soils are mainly found in the flood and deltaic plains of rivers and valleys. Salt accumulation depends on the salinities of the applied water and target soil, and the rate at which salts are leached out of the root zone. If a restricting layer exists close to the soil surface, waterlogging occurs and the accumulation of salt associated with waterlogged soils develops within a comparatively short time. In the absence of such a layer and with large capacity vadose zones, irrigation may be practiced for centuries before problems with surface drainage arise, if ever. Another source of saline water is irrigation drainage effluent, which is often used for irrigation. Although salinity levels may vary, the electrolyte concentrations are usually relatively high.

Under arid or semiarid conditions and in regions of poor natural drainage, salt accumulation is a real hazard. However, salt-affected soils are not confined to semiarid and arid regions. In some other regions, the climate and salt mobility produce saline waters and soil seasonally.

Irrigated agriculture has faced the challenge of sustaining its productivity for generations. Because of natural hydrological and geochemical factors, as well as irrigation-induced activities, soil and water salinity and associated drainage problems continue to plague agriculture.

17.2 Water Quality Criteria for Irrigation

Irrigation water quality is one of the primary considerations ensuring proper water and soil management for crop production. The suitability of water for irrigation is determined by its potential to cause problems to soils and crops and is related to the management practices needed. The quality of water for irrigation is determined mainly by the concentration and composition of solutes present. Most soluble salts in water are composed of the cations Na⁺, Ca²⁺, and Mg²⁺ and anions Cl⁻, SO₄²⁻, and HCO₃⁻. Usually, smaller quantities of K⁺ and NO₃⁻ also occur, as do many other ions and molecules (e.g., B). The concentration of HCO₃⁻ and CO₃²⁻ are pH and CO₂ partial pressure (P_{CO}) dependent.

Bicarbonate is an important parameter as it has a tendency to precipitate Ca and Mg as carbonates (Letey et al., 1985; Amrhein and Suarez, 1987). Calcium reacts with the HCO₃⁻ readily and precipitates as CaCO₃. Although Mg is not as easily precipitated as carbonate, it can accelerate the precipitation of CaCO₃ by replacing Ca on the exchange complex. As Ca and Mg are precipitated, the relative concentration of Na on the exchange phase increases, resulting in soil dispersion, if the total electrolyte concentration is below the critical flocculation concentration (CFC) of the soil clays.

The relative abundance of various ions such as Ca^{2+} , SO_4^{2-} , and HCO_3^- in irrigation water may affect the concentration of soluble salts in the soil solution due to precipitation or dissolution (common ion effect or changing P_{CO_2}). Expressions proposed to account for these effects include the effective salinity, which represents the total salt concentration of irrigation water minus the fraction expected to precipitate as $CaCO_3$, $MgCO_3$, or $CaSO_4 \cdot 2H_2O$.

In irrigation water, cations must balance anions to maintain electroneutrality. The relative abundance of various anions (such ${\rm SO_4^{2^-}, HCO_3^-}$) in irrigation water affects the eventual soluble salt concentration and the subsequent cation concentration ratio in the soil solution. Irrigation with saline water containing excess bicarbonate caused soil pH and sodium adsorption ratio (SAR) to increase, due to precipitation of calcium and magnesium carbonates (Gardner, 2004).

Many problems associated with irrigated agriculture arise from dissolved solute concentration and composition in the water applied. Since all waters contain varying concentrations and different species of solutes, considerable effort has been expended to classify the quality of water in terms of its dissolved solutes composition. The pH of irrigation water is usually not an accepted criterion of water quality because of the disparity in buffer capacity between water and soil.

Salinity is usually expressed as a lumped parameter, for example, specific electrical conductance (EC) in dS m⁻¹, or total dissolved solids (TDS) in mg L⁻¹. No exact relationship exists

between these two measures, but TDS may be approximated by multiplying EC (dS m^{-1}) by a factor varying from 640 in less saline to 800 in hypersaline water.

Generally, the most important water quality parameter for irrigation is the total salt concentration, most commonly measured as EC. The relation between EC (S m⁻¹) and electrolyte concentration (C) of a given salt (mol_c m⁻³) is given by:

$$\Lambda = \frac{EC}{C} \tag{17.1}$$

where Λ is the equivalent conductance (S mol_c⁻¹ m²). The equivalent conductance can be calculated as

$$\Lambda = \Lambda_0 - bC^{1/2} \tag{17.2}$$

where

 Λ_0 is the equivalent conductance at infinite dilution for a given electrolyte

b is a constant whose value depends on the salt

For strong electrolytes, the assumption that b is independent of concentration is valid in the low concentration range. By rearranging Equation 17.1 and introducing Equation 17.2, EC is given by

$$EC = C\Lambda_0 - bC^{3/2}$$
 (17.3)

The relationships between EC (dS m^{-1}) and electrolyte concentration (mmol_c L^{-1}) for various salt solutions are presented in Figure 17.1. The EC of an aqueous electrolyte solution increases

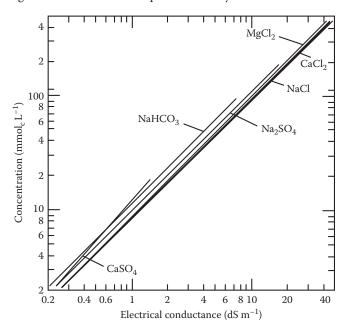

FIGURE 17.1 Relationship between electrolyte concentration and specific EC of various electrolyte solutions at 250°C. (From U.S. Salinity Laboratory Staff. 1954. Diagnosis and improvement of saline and alkali soils. USDA handbook 60. U.S. Government Printing Office, Washington, DC.)

at a rate of approximately 2% C⁻¹. Although the factor for converting EC (dS m⁻¹) to C (mmol_c L⁻¹) depends on the type of electrolyte (e.g., 7.9 for NaCl), a useful approximation is

$$C \text{ (mmol}_{c} L^{-1}) = 10 \times EC \text{ (dS m}^{-1})$$
 (17.4)

when $bC^{3/2} \ll C$.

Usually, classification schemes to define salinity and sodicity hazards are based on broad generalizations regarding crops to be grown, soil properties, irrigation management, and climate. Initial schemes were developed using various expressions for salinity and sodicity criteria (U.S. Salinity Laboratory Staff, 1954) but problems have been encountered, particularly as far as sodicity is concerned (Summer and Naidu, 1998). A classification based on specific use factors that takes salt tolerance of plants into account was proposed by Bernstein (1967) and Carter (1969). The general water classes in relation to their salt concentrations are presented in Table 17.1. This classification was based only on irrigation water quality and plant sensitivity to salinity.

The salinity of irrigation water can be assessed by relating irrigation water salinity (EC_{iw}), leaching fraction (LF), average root zone salinity, and crop salt tolerance (Rhoades, 1982). The LF can be estimated using Equation 17.5

$$LF = \frac{EC_{iw}}{5EC_e - EC_{iw}}$$
 (17.5)

where

 EC_{iw} is the electrical conductance of the irrigation water (dS $m^{-\text{l}})$

 $\mathrm{EC_e}$ is the average electrical conductance of the soil water in the root zone (dS $\mathrm{m^{-1}})$

The relationships between the average salinity in the root zone (EC_e) and EC_{iw} for each LF are presented in Figure 17.2 in which the horizontal lines indicate crops that can be grown successfully without decreases in yield from salinity. For example, if EC_{iw} is 5 dS m⁻¹ and LF is 0.2, only tolerant crops can be grown without decreasing yield. However, if LF is 0.4, moderately tolerant plants can be grown successfully. Thus, assessing the effects of salinity as a water quality parameter depends on the soil, the crop, available water, irrigation management, and the decrease in yield that can be tolerated.

In addition to the total salinity hazard of irrigation water, the ionic composition must be also considered. A useful index for predicting excessive exchangeable Na is the SAR, defined as

$$SAR = \frac{(Na^{+})}{(Ca^{2+})^{1/2}}; \quad 0 \le SAR \le \infty$$
 (17.6)

The activity of Na and Ca ions is given in mmol L⁻¹.

The U.S. Salinity Laboratory (1954) assumed that Mg behaves similar to Ca^{2+} in the adsorbed phase and defined $SAR = (Na^+)/(Ca^{2+} + Mg^{2+})$. Sposito and Mattigod (1977)

TABLE 17.1	Water Classes in	Relation to	Their Salt (Concentration

Class of Water	Electrical Conductivity dS m ⁻¹ (25°C)	Comments
Low salinity	0-0.4	These waters can be used for irrigating most crops grown on most soils with a low probability that salt problems will develop. Some leaching is required, but this generally occurs with normal irrigation practices
Moderate salinity	0.4–1.2	These waters can be used if a moderate amount of leaching occurs. Plants with moderate salt tolerance can be grown in most instances without special practices for salinity control. Producing field beans and potatoes with these waters is hazardous and requires special management practices
High salinity	1.2-2.25	These waters should not be used on soils with restricted drainage. Plants tolerant to salinity should be grown. Excess water must be applied for leaching
Very high salinity	2.25–5.0	These waters are suitable for irrigation under special circumstances. Adequate drainage is essential. Only very salt tolerant crops should be grown. Considerable excess water must be applied for leaching

Lethbridge, AB, Canada.)

distinguished between the true SAR (SAR_t), which includes free ion activities and practical SAR (SAR_p), uncorrected for ion pairs, complexes, or activity coefficients. The relationship between the two parameters is given in Figure 17.3. The SAR_p is generally less than the SAR_t because of the greater effects of ion pair, complex, and activity coefficient corrections on Ca²⁺ and Mg²⁺ than on Na⁺. The regression equation between the two parameters is

$$(SAR)_t = 0.08 + 1.115 (SAR)_p$$
 (17.7)

The ionic strength (I) of a solution is needed in order to calculate the ion activity coefficient. Calculation of I is complicated by the

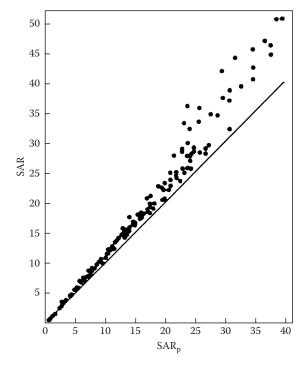

FIGURE 17.3 The relationship between the SAR and the practical SAR for 161 soil solutions and water extracts. The straight line represents a 1:1 functional relationship between SAR and SAR_p. (Reprinted from Sposito, G., and S.W. Mattigod. 1977. On the chemical formation of the sodium adsorption ratio. Soil Sci. Soc. Am. J. 41:323–329. With permission of the Soil Science Society of America.)

presence of ion pairs and complexes in soil solutions. However, values of I (mol L⁻¹) can be calculated with sufficient accuracy for most applications from the relation that includes corrections for ion pairs and complexes and is valid for most natural waters (Griffin and Jurinak, 1973):

$$I = 0.013 * EC$$
 (17.8)

where EC is the specific electrical conductance (dS m⁻¹).

The relationship between exchangeable sodium percentage (ESP) and SAR is given by the mass action equation:

$$ESP = \frac{100 * K * SAR}{1 + K * SAR}$$
 (17.9)

where K is the reaction coefficient (mmol L^{-1})^{-1/2}. When K·SAR \gg 1, 1 can be neglected and

$$ESP \to 100$$
 (17.10)

But when $K \cdot SAR \ll 1$, then $K \cdot SAR$ can be neglected in the denominator and

$$ESP \rightarrow 100 * K * SAR \tag{17.11}$$

Therefore, the Na⁺ concentration of irrigation water alone is not sufficient to estimate the potential sodicity hazard. From Equation 17.9, the effective diagnostic criteria for estimating the sodicity status of a given soil are the SAR of the irrigation water and the reaction coefficient (K) for Na–Ca exchange of the soil. For example, the relationship between ESP and SAR of a soil at equilibrium for various reaction coefficients is given in Figure 17.4. These calculations indicate that the K for Na–Ca exchange in the exchangeable cation complex of the clays is an important criterion in evaluating water quality for irrigation for a given soil. It is important to note that for soils having K > 0.01 (mmol L⁻¹)^{-1/2}, there is only one SAR value that is equal to ESP for each K (the linear line). Positive and negative deviations are observed when SAR is below or above this value, respectively. However, for many

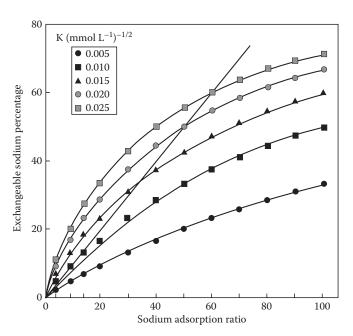

FIGURE 17.4 Relationship between exchangeable sodium percentage (ESP) and sodium adsorption ratio (SAR) for various adsorption coefficients.

montmorillonitic soils, having a K value \sim 0.015 (mmol L⁻¹)^{-1/2}, the deviation of ESP from SAR of the soil solution is small, up to SAR 30

Since the SAR is usually determined on an irrigation water or saturation extract of a soil (by adding distilled water), there is an inherent problem of relating these values to the condition that exists in the field. By neglecting the effect of salt precipitation or dissolution, mineral weathering, and the uptake of salts by plants, salt concentration in soil solution increases due to root water uptake and water evaporation from bare soil without changing the relative concentrations among the ionic species in soil solution. The SAR value, however, increases proportionally to the square root of the increase in the total concentration. Thus, if the total electrolyte concentration in solution increases by a factor of d, the SAR will increase by the factor of $(d)^{1/2}$. Since the soil ESP increases with the increase in SAR, it is obvious that the resultant ESP would be greater than the ESP expected from the SAR of the irrigation water. This trend has been observed in lysimeters and field experiments (Rhoades, 1968).

It is obvious, therefore, that in attempting to assess the sodicity hazard in soils, texture, clay mineralogy, SAR, and the total electrolyte concentration of the percolating solution should be taken into consideration. Other important parameters needed for water quality assessment for irrigation are soil physical properties, pH, precipitation and dissolution processes of primary and secondary minerals and salts in soil, specific toxic ion concentrations in relation to the affinity of soil constituents to adsorbdesorb, as well as soil and irrigation management (e.g., presence of soil amendments such as gypsum, LF, irrigation methods). A comprehensive irrigation water classification scheme incorporating all these factors has not yet been developed. In contrast to previous studies, Gardner (2004) reported that SAR of the soil extracts was not correlated with ES and soil pH. The SAR values rose with irrigation once pH exceeded 8, suggesting that carbonate formation was incomplete due to insufficient bicarbonate.

17.3 Effect of Salinity on Soil Physical Properties

Considerable progress has been made in managing and controlling salinity and sodicity in irrigated lands. However, because of natural hydrological and geochemical factors, as well as irrigation-induced activities, soil and water salinity and associated drainage problems continue to plague agriculture.

The ionic composition and concentration of the soil solution affects soil physical properties. The accumulation of dispersive cations, such as Na (and sometimes Mg and K), promotes clay swelling and/or dispersion altering the geometry of soil pores which, in turn, affects intrinsic soil permeability, water retention, and crop productivity.

The adverse physical condition imparted to soils by high ESP on the exchange complex can be partially overcome by a sufficiently high concentration of salts. Smectites are the dominant clay mineral in many semiarid and arid regions and they

determine much of the physical properties of soils, such as swelling and dispersion, due to the large specific surface area and the electrostatic charge. These two processes determine, to a large extent, soil structure, hydraulic properties, and soil water retention.

The Van der Waals attraction energy, V_A , between two semiinfinite plates such as 2:1 clay mineral, is given by

$$V_{A} = -\frac{A}{12\pi} \left[\frac{1}{h^{2}} + \frac{1}{(h+2t)^{2}} + \frac{1}{(h+t)^{2}} \right]$$
 (17.12)

where

A is the Hamaker constant (2.2×10^{-20} J, Israelachvili and Adams, 1978)

h is the distance between the surfaces of the plates t is the thickness of the clay plate

The Van der Waals forces are independent of the charge density on the clay and the composition and concentration (<1 mol dm⁻³) of the electrolytes in suspension in the distance range 1–15 nm between two adjacent clay plates (Israelachvili and Adams, 1978).

The repulsion energy $V_R(d)$ between two clay platelets can be computed from the diffuse double layer theory (Lyklema, 1982),

$$V_{R(d)} = \frac{64 \, \text{nkT}}{\chi} \left[\tanh \left(\frac{\text{Ze} \, \psi_s}{4 \, \text{kT}} \right) \right]^2 e^{-2\chi d} \tag{17.13}$$

where

n is the number of cations per unit volume

k is the Bolzmann constant

T is the temperature

Z is the cation valency

 ψ_s , is the Stern layer potential

d is the distance from clay surface to the midway plane between two parallel platelets

e is the electron charge

χ is the reciprocal Debye length, given by

$$\chi = \left(\frac{2e^2nZ^2}{DkT}\right)^{1/2}$$
 (17.14)

where D is the dielectric constant of the medium and the other symbols are as defined above.

The repulsion energy depends on charge density of the plate and composition and concentration of the electrolyte in suspension.

Montmorillonite platelets in aqueous suspension may flocculate in three possible modes of particle association (Van Olphen, 1977): (1) association between siloxane planes of two parallel platelets (FF), (2) association between edge surfaces of neighboring particles (EE), and (3) association between an edge surface and a siloxane planar surface (EF). In the presence of electrolyte (e.g., NaCl) at low concentration, the double layers on the

Na-montmorillonite particles are well developed and osmotic repulsion prevents particle association. Thus, a stable suspension of individual platelets is obtained (Van Olphen, 1977). As the concentration of NaCl in the suspension increases, double layers at both the planar and the edge surfaces are compressed, and at the CFC, both EF and EE association can occur (Heller and Keren, 2001). As the electrolyte concentration increases further, the FF mode of particle association occurs, and "oriented aggregates" are formed (Keren et al., 1988).

The mechanism of swelling has as its analogy the osmotic characteristics of a semipermeable membrane. The ions between the clay platelets in the exchange phase are constrained there by the electrical attraction of the negatively charged clay surfaces. Thus, under a nonequilibrium condition, the gradient for water movement is from the bulk solution to the inner platelet region since the concentration of ions is greater there. The movement of the water into this region creates a hydrostatic pressure that forces the clay to expand and swell. A Na-soil, with a larger number of ions in the inner platelet region coupled with their weak interaction with the clay platelets, is more susceptible to swelling and dispersion than a Ca soil. Therefore, excess adsorbed Na most adversely affects the permeability of the soil (McNeal et al., 1968; Frenkel et al., 1978; Keren and Singer, 1988), which decreases with the square of the pore radius. Swelling, or the movement of clay, or both, significantly affects permeability. The extent of swelling, or dispersion of clays, or both, depends on the mineralogy of the clays, the composition of the adsorbed ions, the concentration of salt in the solution, and the content of hydroxy-aluminum and hydroxy-iron (Shainberg et al., 1971; Oster et al., 1980; Goldberg and Glaubig, 1987; Keren and Singer, 1988, 1989, 1991). The swelling of clay increases as the electrolyte concentration of the solution decreases. The dispersion of clay occurs only at electrolyte concentrations below the CFC of the clay. The degree to which the clay swells before the solution is replaced with one that has an electrolyte concentration below the clay's FV determines whether clay particles will move into the conducting pores and leave the root zone, or remain trapped in the narrow pores and decrease the hydraulic conductivity (HC) of the soil (Keren and Singer, 1988).

When leached with water of low salt concentrations, the soil's potential for mineral weathering, that is, for releasing electrolytes, influences the HC. Calcareous soils and soils with feldspar minerals release electrolytes into the solution in the presence of exchangeable Na. If the electrolyte concentration of the soil solution is maintained above the CFC, the clay does not disperse and the HC changes minimally. The electrolyte concentration of the applied water controls the HC of soils without weathered minerals. When these soils are leached with low salt waters (below CFC), clay disperses and the HC decreases.

The HC of a soil can be maintained even at high ESP levels provided that the EC of the percolating solution is above a threshold value. Conversely, when irrigation water with very low EC is used, even an ESP = 5 caused a twofold decrease in HC (McIntyre, 1979). Thus, in arid and semiarid regions where irrigation with saline water is practiced and soils are saline and sodic, the deleterious effect of exchangeable Na is more evident

during the irrigation with high quality water (or rain) than that during irrigation with saline water.

Infiltration rate (IR) also depends on EC and ESP of the soil (Agassi et al., 1981) but is more sensitive to increasing ESP than the HC, because the energy of impacting raindrops promotes dispersion allowing a seal to form at the surface (Oster and Schroer, 1979). The permeability of the seal decreases with decreasing EC at the soil surface. Thus, when low EC water is applied (rain or snow), salt concentration at the soil surface will be low even in soils containing weatherable minerals such as CaCO₃, and clay dispersion takes place. Consequently, sodicity damage to soil will not take place during the irrigation season when EC in the applied water is high enough to counter the dispersive effect of the exchangeable Na, but will occur during the rainy season (or irrigation with high quality water) when EC in the soil decreases to values that allow clay to disperse. Thus, the salinity of the applied water is an important parameter in assessing sodicity hazard.

Successful irrigated agriculture, however, requires permanent control of salinity, sodicity, and B levels in soil and irrigation water. Reclamation of affected soils by means of improved drainage, chemical treatments, and leaching of salts (Keren and Miyamoto, 1990) can reduce natural hazards creating stable conditions for intensive cropping.

17.4 Boron-Soil Interaction

When irrigation water containing boron enters soil, boron can be adsorbed on soil constituents or desorbed into soil solution, depending on the boron concentration in the irrigation water and the level of native adsorbed boron. The time required to reach a steady-state boron concentration in the soil depends on the boron concentration in relation to that before irrigation, the LF, and adsorption capacity of the soil. Even if irrigation water does not contain toxic concentrations of boron, its retention by the soil can lead to accumulation approaching harmful levels in the long term if LF (including rainfall) is insufficient.

The main boron species likely to occur in soil solution are B(OH)₃ and B(OH)₄ and the ratio between them is pH dependent. Boron can be specifically adsorbed by different clay minerals, oxyhydroxides of Al, Fe, and Mg, and organic matter, which vary in their adsorption capacities (Goldberg and Glaubig, 1985; Keren and Bingham, 1985). The adsorption depends on the equilibrium boron concentration in the soil solution and pH (Bingham et al., 1971; Mezuman and Keren, 1981; Goldberg and Glaubig, 1985). Increasing pH enhances boron adsorption by soils, clays, and Al and Fe oxides showing a maximum in the alkaline pH range. Boron adsorption isotherms for a given soil at various pH values are presented in Figure 17.5 (Mezuman and Keren, 1981) as an example. Keren and Bingham (1985) have reviewed the mechanisms and factors that affect the adsorption and desorption of boron by soil constituents.

In assessing boron concentration in irrigation water, the physical-chemical characteristics of the soil must be taken into consideration because of the interaction between boron and soil. Boron sorption and desorption from soil adsorption sites

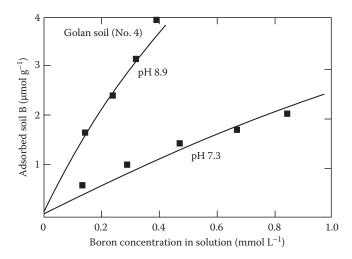

FIGURE 17.5 Adsorbed amount of boron on clay soil as a function of the total boron solution in 0.01 N BAcl2 solution and of pH. (Reprinted from Mezuman, U., and R. Keren. 1981. Boron adsorption by soils using a phenomenological adsorption equation. Soil Sci. Soc. Am. J. 45:722–726. With permission of the Soil Science Society of America.)

regulate the boron concentration in soil solution depending on the changes in solution boron concentration, the affinity of soil for boron species, soil solution pH, and competing ion concentration. Thus, adsorbed boron may buffer fluctuations in solution boron concentration. When irrigation with water high in boron is planned, special attention should be paid to this interaction because of the narrow range between levels causing deficiency and toxicity symptoms in plants.

17.4.1 Boron Adsorption by Soil Constituents

Boron can be specifically adsorbed by different clay minerals that vary in their adsorption capabilities. Boron adsorption isotherms for Ca saturated with montmorillonite, illite, and kaolinite at constant pH and ionic strength were conducted by Keren and Mezuman (1981). It is evident that on a weight basis, illite is the most reactive among these clay minerals, whereas kaolinite is characterized by the lowest level of boron adsorption. Although boron adsorption by illite is much greater than by montmorillonite, the total surface area of montmorillonite is much greater than that of illite. Assuming that (i) most of the boron adsorption by montmorillonite or illite takes places at the broken edges and (ii) the surface area of these broken edges is about 8 m² g⁻¹ (Dyal and Hendricks, 1950), the boron concentration at the clay surface (based on the edges alone) should be about 6.6×10^{-5} mol g-1 clay. This value is on the same order of magnitude as that found for illite $(1.5 \times 10^{-5} \text{ mol g}^{-1})$ by Keren and Mezuman (1981). Moreover, the calculated maximum boron adsorption values based on edge surface areas for montmorillonite and illite are very close: 1.47 and 1.88 µmol m⁻², respectively. This suggests that boron is adsorbed on the clay edges rather than on the planar surfaces (Keren and Talpaz, 1984). The boron adsorption process can be explained by the surface complexation approach, in which the surface is considered as a ligand (Keren et al., 1994). Such specific adsorption, which occurs irrespective of the sign of the net surface charge, can occur theoretically for any species capable of coordination with the surface metal ions. However, because oxygen is the ligand commonly coordinated to the metal ions in clay minerals, the boron species $\mathrm{B(OH)_3}$ and $\mathrm{B(OH)_4}^-$ are particularly involved in such reactions. Possible surface complex configurations for boron—broken edges of clay minerals—were suggested by Keren et al. (1994).

Hydroxy oxides of AI, Fe, and Mg adsorb large amounts of boron (Keren and Gast, 1983; Goldberg and Glaubig, 1985, 1988). In view of the chemical and structural similarities between clay edges and hydroxy-AI, Keren and Gast (1983) compared boron adsorption by these two surfaces. They showed that the hydroxy-AI exhibited a marked affinity for boron. The amount of boron adsorbed by hydroxy-AI at pH 9.5 was about 7.5 times greater than by Ca-montmorillonite under the same conditions (Keren and Mezuman, 1981; Keren and Gast, 1983). Magnesium hydroxide has an appreciable capacity for boron adsorption, which is not affected by aging (Rhoades et al., 1970). Rhoades et al. (1970) concluded that arid-zone soils can have appreciable boron adsorption capacities in their silt and sand fractions as well as clay fractions. The site of this adsorption appears to be hydroxy-magnesium clusters or coatings that exist on the weathering surfaces of ferro-magnesium minerals. It can be concluded that the presence and amount of hydroxy-Al, -Fe, and -Mg have a substantial role in boron adsorption by soils.

Organic matter is an active portion of a soil. Although most cultivated soils contain only 1%-5% organic matter (mostly in the top 30 cm of soil), this small amount can significantly modify the soil's chemical properties. The humus has a chemical affinity for boron and it appears to have an important role in the retention of boron by soils (Parks and White, 1952). Hydrogensaturated humus was found to retain boron approximately twice the concentration of the calcium-saturated humus (Parks and White, 1952). The complex formation between diols and boron (Boeseken, 1949) can explain the results observed by Parks and White (1952) for humus. The adsorptivity of organic matter for boron is much higher than that of montmorillonite, kaolinite, or illite (Keren and Bingham, 1985; Yermiyahu et al., 1988). Boron adsorption by dissolved organic matter extracted from effluent of a municipal sewage plan was 294-333 mg kg⁻¹ (Communar and Keren, 2008). The interaction of effluent-dissolved organic matter with boron may play an important role in assessing boron solution concentration and boron transport in soil.

17.4.2 Kinetics and Mechanisms of Boron Adsorption

Boron is adsorbed mainly on the edge surfaces of the 2:1 clay minerals (Keren and Talpaz, 1984; Keren and Bingham, 1985; Keren and Sparks, 1994). Since the negative electrical field (e.g., emanating from the particle face of montmorillonite) extends to the edge surface region (Secor and Radke, 1985), it influences edges, making them less accessible to approaching borate anions. The forward adsorption rate constant, k₁, for boron

adsorption by pyrophyllite was $10^{4.26}$ L mol $^{-1}$ and the backward rate constant, k_{-1} , for the desorption was $10^{1.11}$ S $^{-1}$ (Keren et al., 1994). The intrinsic equilibrium constant obtained from the kinetic measurements ($\log_{10} K_{\rm kinetic} = 3.15$) agreed relatively well with that calculated from the static studies ($\log_{10} K_{\rm static} = 3.51$). The reaction scheme for the boron–pyrophyllite interaction was suggested as (Keren et al., 1994)

$$S(OH)_2 + B(OH)_4 \leftrightarrow SO_2 - B(OH)_2 + 2H_2O$$
 (17.15)

or

$$S(OH)_2 + B(OH)_4 \Leftrightarrow SO_2H-B(OH)_3 + H_2O$$
 (17.16)

17.4.3 Boron Adsorption Modeling

The surface complex approach assumes that the surface consists of discrete sites that interact with the adsorbate specifically. These interactions would include the attractive short-range dispersion forces and hydrogen bonding in the interfacial regions. It is possible that the hydroxyl groups in the coordination sphere of the adsorbate species may act as bridging ligands between the adsorbate and adjacent surface groups. Thus, boron can be specifically adsorbed on mineral surfaces and hydroxy-Al polymers through a mechanism referred to as ligand exchange, whereby the adsorbed species displace OH- (or H₂O) from the surface and form partly covalent bonds with the structural cations (Hingston et al., 1974). Such specific adsorption, which occurs irrespective of the sign of the net surface charge, can occur theoretically for any species capable of coordination with the surface metal ions. However, because oxygen is the ligand commonly coordinated to the metal ions in clay minerals, the boron species, B(OH)₃ and B(OH)₄, are particularly involved in such reactions. Results by Keren and O'Connor (1982) and Keren et al. (1994) support this approach.

The suggested mechanism for the reaction of organic sites with boron is similar to the hydroxyl replacements suggested for clay minerals. Forsyth (1950) studied the composition of the soluble polysaccharide fraction of soil organic matter and found that upon hydrolysis various sugars such as galactose, glucose, mannose, arabinose, xylose, and glucoronic acid were produced. All these compounds meet the requirements for complex formation with boric acid, and most of them have been demonstrated to react with boric acid (Boeseken, 1949).

Boron adsorption by soils (Bigger and Fireman, 1960; Elrashidi and O'Connor, 1982) and clays (Hingston, 1964; Sims and Bingham, 1967) appears to obey the Langmuir equation

$$\frac{x}{m} = \frac{k * b * c}{1 + k * c}$$
 (17.17)

where

x is the amount of boron adsorbed

m is the amount of adsorbent

k is the affinity coefficient of the adsorbent to boron

b is the maximum capacity of the adsorbents for monolayer coverage

c is the equilibrium boron concentration in solution

This equation was found to be valid for some conditions but deviations occur at higher solution concentrations and at higher pH values (Hingston, 1964). This adsorption model has two disadvantages: (1) it does not account for the existence of two boron species of different affinities for the clay, and their varying proportion in the equilibrium solution with varying pH; and (2) different values of the Langmuir coefficients, namely maximum adsorption and binding energy constants, must be assigned to predict boron adsorption at any given pH value.

Another approach for describing boron adsorption by clays, hydroxy-AI, and soils has been derived by Keren et al. (1981). Their model is based on the assumption that $B(OH)_4$, and OH^- are all competing for the same adsorption sites. The equilibrium constant for adsorption of each of the three species is given by

$$K_{i} = \frac{(M_{i})(1 - \theta_{i})}{\theta_{i}} \tag{17.18}$$

where

K_i is the equilibrium constant

M_i is the activity of the i th form

 θ_i is the mole fraction of the i th form adsorbed

 $1 - \theta_i$ is the mole fraction of the adsorber not accounted for

When one combines Equation 17.16 for the three species $B(OH)_3$, $B(OH)_4$, and OH^- and introduces $\theta_i \equiv Q_i/T_m$ where Q_i is the adsorption of the species M_i and T_i is the total boron adsorption capacity coefficient, then the adsorption of species M_i can be described by

$$Q_{i} = \frac{T_{m}K_{i}(M_{i})}{1 + \sum_{j=1}^{3} K_{j}(M_{j})}$$
(17.19)

where K_i (or K_i) is the equilibrium constant.

The general form of Equation 17.17 written specifically for boron adsorption is given in Equation 17.18 (Keren et al., 1981):

$$Q_{BT} = \frac{T_{m}(K_{HB}(HB) + K_{B}(B))}{1 + K_{HB}(HB) + K_{B}(B) + K_{OH}(OH)}$$
(17.20)

where

 T_m is the maximum boron adsorption

 K_{HB} , K_{B} , and K_{OH} are affinity coefficients related to the binding energy for the species $B(OH)_3$, $B(OH)_4^-$, and OH^- , respectively

(HB), (B), and (OH) are the solution activities of the above species, respectively

Equation 17.20 can be rearranged to relate total amount of adsorbed boron, Q_{BT} , to total boron in the suspension,

 Q_T (adsorbed boron + boron in solution), and to solution-to-adsorbent ratio, R:

$$Q_{BT} = T_{m} \left\{ 1 + \frac{PR}{F(Q_{T} - Q_{BT})} [1 + K_{OH}(OH)] \right\}^{-1}$$
 (17.21)

Here $P = 1 + K_h 10^{14}(OH)$; K_h is the hydrolysis constant of the reaction

$$B(OH)_3 + 2H_2O \Leftrightarrow B(OH)_4^- + H_3O^+$$
 (17.22)

and $F = K_{HB} + K_B(P - 1)$.

Keren et al. (1981) estimated the affinity coefficients as well as the maximum boron adsorption values (Equation 17.20) from experimental results using a best fit procedure (Mezuman and Keren, 1981).

Soil pH is one of the most important factors affecting boron adsorption. Increasing pH enhances boron adsorption, showing a maximum in the alkaline pH range (Mezuman and Keren, 1981). The response of adsorbed boron on soils to variation in pH can be explained as follows. Below pH 7, B(OH)₃ predominates and since the affinity of the clay for this species is relatively low, the amount of adsorption is small. Both B(OH)₄- and OH- concentrations are low at this pH; thus, their contribution to total boron adsorption is small despite their relatively strong affinity for the soil. As the pH is increased to about 9, the B(OH)₄- concentration increases rapidly. Since the OH- concentration is still low relative to the boron concentration, the amount of adsorbed boron increases rapidly. Further increases in pH result in an enhanced OH- concentration relative to B(OH)₄-, and boron adsorption decreases rapidly due to the competition by OH- at the adsorption sites.

A constant capacitance model was developed by Stumm, Schindler, and their coworkers (Schindler and Gamsjager, 1972; Hohl and Stumm, 1976; Stumm et al., 1976; Stumm et al., 1980) for hydrous oxides—aqueous solution interface—assuming that the adsorption mechanism is ligand exchange that takes place in the inner sphere and the relationship between surface charge and surface potential is linear. This model can describe boron adsorption by soil over changing conditions of solution pH and boron concentration (Goldberg et al., 2000). The surface complexation reactions for the application of this model to boron are

$$SOH + H^{+} \Leftrightarrow SOH_{2}^{+}$$
 (17.23)

$$SOH \Leftrightarrow SO^- + H^+$$
 (17.24)

$$SOH + H_3BO_3 \Leftrightarrow SH_2BO_3 + H_2O \qquad (17.25)$$

$$SOH + H_3BO_3 \Leftrightarrow SH_3BO_4^- + H^+$$
 (17.26)

Where SOH represents the surface functional group of surface hydroxyl ion bound to Al or Fe in the oxide mineral or an

aluminol group on the clay mineral. The intrinsic conditional equilibrium constant expressions describing these reactions are (Goldberg and Glaubig, 1985)

$$K_{+}(int) = \frac{[SOH_{2}^{+}]}{[SOH][H^{+}]} exp \left[\frac{F\psi}{RT}\right]$$
 (17.27)

$$K_{-}(int) = \frac{[SO^{-}][H^{+}]}{[SOH]} exp \left[\frac{-F\psi}{RT}\right]$$
 (17.28)

$$K_B(int) = \frac{[SH_2BO_3]}{[SOH][H_3BO_3]}$$
 (17.29)

$$K_{B-}(int) = \frac{[SH_3BO_4^-][H^+]}{[SOH][H_3BO_3]} exp \left[\frac{-F\psi}{RT}\right]$$
 (17.30)

where

square brackets indicate concentrations (mol L-1)

F is the Faraday constant (C mol_c⁻¹)

 ψ is the surface potential (V)

R is the molar gas constant (J mol⁻¹ K⁻¹)

T is the absolute temperature (K)

The computer program FITEQL (Westall, 1982) can be used to fit the intrinsic boron surface complexation constant to experimental adsorption data. This model has successfully described boron adsorption on aluminum and iron oxide minerals (Goldberg and Glaubig, 1985, 1988), clay minerals (Goldberg and Glaubig, 1986), and soils (Goldberg et al., 2000).

17.4.4 Boron Transport Modeling

Two-site model (LE-NE) accounting for the existence of equilibrium and nonequilibrium adsorption sites for boron and the two-domain two-rate model (TD-TR) were suggested by Communar and Keren (2005, 2006). The Keren model (Equation 17.20) was introduced into these two models. These models were very successful in the simulation of boron transport in soil.

A transient-state solute transport model TETrans (Corwin et al., 1991) was also used to simulate boron movement through the root zone (Corwin et al., 1999). Because the ability to simulate water flow has been evaluated already for this model, the focus of their study centered around the performance of various functional models of boron adsorption used as subroutines within the TETrans model, including the (1) Freundlich adsorption isotherm equation, (2) Langmuir adsorption isotherm equation (3) kinetic Freundlich equation, (4) temperature-dependent Langmuir equation, and (5) pH-dependent Keren boron adsorption models, the pH-dependent Keren boron adsorption model performed the best in simulating boron transport in soil.

17.5 Effects of Salinity and Boron on Plants

17.5.1 Crop Tolerance to Salinity

When soluble salt accumulates in a soil to a level harmful to the growth of particular plants, the soil is termed saline. The composition and concentration of salts in the soil solution adversely influence plant growth through (1) osmotic effects, which limit the ability of plants to absorb water from the soil solution; (2) specific ion effects; and (3) changes in soil physical and chemical properties that can have long-term detrimental effects on crop production.

Threshold concentrations for classifying crop tolerance to salinity are (Maas, 1990) (1) sensitive (<1.5 dS m⁻¹) (bean, clover, carrot, lettuce); (2) moderately sensitive (1.5–3.0 dS m⁻¹) (corn, alfalfa, broccoli, potato); (3) moderately tolerant (3–6 dS m⁻¹) (soybeans, wheat, squash); and (4) tolerant (6–10 dS m⁻¹) (barley, sorghum, sugar beet) (1 dS m⁻¹ ~ 350 mg L⁻¹ Cl⁻). Salinity refers to concentrations of soluble salts that are so high as to negatively impact plant growth. In the absence of specific ion effects, crop growth reduction due to salinity is related to the osmotic potential, ψ_o (bar), which is a function of EC_e (dS m⁻¹) at 25°C as follows:

$$\psi_{\rm o} = -0.39 \, \rm EC_{\rm e}$$
 (17.31)

This relationship is valid for EC_e in the range 3–30 dS m⁻¹. Because decreasing y_o (increasing absolute value) has the net effect of reducing water availability, plants growing on saline soils often appear to be suffering from drought.

Relative crop yield as a function of EC_e for various crops is given in Figure 17.6 (Maas and Hoffman, 1977). Relative yield (Y) was calculated from the relation

$$Y = 100 - B (EC_e - A)$$
 (17.32)

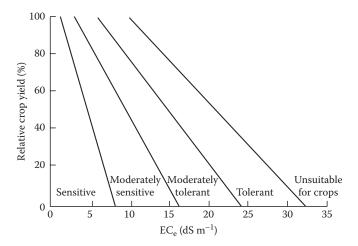

FIGURE 17.6 Divisions for classifying crop tolerance to salinity. (Reprinted from Maas, E.V., and G.J. Hoffman. 1977. Crop salt tolerance-current assessment. J. Irrig. Drain. Div. ASCE 103:115–134. With permission of the Soil Science Society of Civil Engineers.)

where

 EC_e is the electrical conductance of the soil saturation extract solution (dS m^{-1})

A is the salinity threshold value (dS m⁻¹)

B is the percent yield decrease per unit salinity increase

The threshold salinity value and productivity decrease as a percentage of normal yield for each unit increase in EC_e have been summarized by Maas (1990). Such information is useful in selecting crops for growth under anticipated salinity conditions. However, the sensitivity of crops to soil salinity often changes from one stage of growth to the next.

Any assessment of water suitability for irrigation must be made in relation to crop tolerance to salinity, irrigation and soil management (LF, irrigation methods, soil properties, etc.), and yield decreases that can be tolerated. This can be shown (Figure 17.2) by relating the EC_e in the root zone to EC_{iw} at a LF appropriate for conventional irrigation management (such as furrow or flood), which allows for considerable drying between applications (Rhoades, 1982). Because most plants are relatively salt tolerant during germination, but more sensitive during emergence and early growth, it is imperative to keep salinity in the seedbed low after germination.

Varietal differences in salt tolerance often occur. Rootstocks affect the salt tolerances of tree and vine crops because they regulate the uptake and translocation of potentially toxic ions, such as Na and Cl, to the shoots.

Salt tolerance depends on the method of irrigation and its frequency. As water becomes limiting, plants experience stresses from low matric and osmotic potentials. Available salt tolerance data are most appropriate for crops irrigated by furrow or flood irrigation under conventional management. Because salt concentrations in irrigated profiles change constantly (up to several fold), the plant is most responsive to salinity in that part of the root zone where maximum water uptake occurs.

Sprinkler irrigated crops are potentially subject to additional damage by foliar salt uptake and burn from spray contact on the foliage. Susceptibility to foliar salt injury depends on leaf characteristics and rate of absorption and does not correlate with general salt tolerance. Although injury caused by spray on foliage depends on weather and water stress, relatively little information is available for predicting yield losses. Increase in frequency of sprinkling, temperature, and evaporation leads to increased salt concentration on the leaves and damage (Maas, 1986). Climate is a major factor affecting salt tolerance. Most crops can tolerate greater salt stress under cool humid than hot dry conditions. Yield is reduced more by salinity when humidity is low.

Substantial progress has been made in developing empirical models to relate crop yields and irrigation management under saline conditions. Childs and Hanks (1975) extended the production function model of Bresler and Hanks (1969) and Nimah and Hanks (1973a,b) to consider the effect of salinity and to compute yield. They reported a good correlation between computed and measured transpiration and predictions for crops

with different rooting depths, different initial soil salinities, and multiyear cropping. Computed and measured data correlated well when levels of salinity were low but yields were overestimated when salinity was high (Wolf, 1977).

An empirical relationship between yield and water potential (matric and osmotic) after converting salt concentration to osmotic potential is (van Genuchten and Hoffman, 1984)

$$Y = \frac{Y_{\rm m}}{1 + \left(\Pi/\Pi_{50}\right)^{\rm p}} \tag{17.33}$$

where

Y is yield

Y_m is maximum yield under nonsaline conditions

 Π and Π_{50} are the osmotic potential of the solution and the osmotic potential at which the yield is reduced by 50%, respectively

p is an empirical constant

This model described salt tolerance data as well or better than the model of Maas and Hoffman (1977). Solomon (1985) and Letey et al. (1985) presented a seasonal water-salinity production function based on the response of crops to water and salts. Measured and computed yields for several crops correlated well (Letey et al., 1985; Letey and Dinar, 1986).

The dynamic models described above assume a unique relationship between yield and evapotranspiration (ET) for a given crop and climate that is independent, regardless of whether the water stress leading to the reduced ET is caused by deficit water supply or excess salinity. Letey and Knapp (1991) discussed the usefulness and limitations of these models. Crop-water production functions can be used to evaluate the losses from increased salinity in soil and water, the potential for reuse of saline drainage waters, the demand for water in irrigated agriculture, and changes in irrigation and drainage policy.

17.5.2 Specific Molecule and Ion Effects on Plants

In addition to the osmotic and soil structure effects, some dissolved molecules and ions (boron, Cl, Na) can cause specific detrimental effects on crops. Toxicity occurs within the crop as the result of uptake and accumulation of these elements within plant tissue. Thus, an excess of these ions in irrigation water may be toxic to various plant physiological processes and may also cause nutritional disorders. In terms of saline soils, B is probably the most important. The effect of salinity on plant physiology and biochemistry is reviewed by Lauchli and Epstein (1990).

Boron has a marked effect on plants, with the optimum range in soil between deficiency and toxicity being very narrow. Boron deficiency is found primarily in humid regions or in sandy soils, while toxicity occurs most frequently in arid and semiarid regions due to high soil boron or boron additions in irrigation water.

The threshold boron concentration for irrigation water (maximum permissible concentration for a given crop that does not reduce yield or lead to injury symptoms) ranged from as low as 0.3 for sensitive to 2.0 mg $\rm L^{-1}$ for tolerant crops (U.S. Salinity Laboratory Staff, 1954). Yield decreases due to boron toxicity can be evaluated from (Bingham et al., 1985) the following equation:

$$Y = 100 - m (X - A)$$
 (17.34)

where

Y is the relative yield (for X³A)

m is the decrease in yield per unit increase in boron concentration

X is the boron concentration in the soil solution

A is the maximum boron concentration that does not reduce yield (threshold value)

Boron threshold concentrations and the slopes of yield reduction as a function of boron concentration for a limited number of crops are given in Table 17.2. A more extensive listing is given by Keren and Bingham (1985).

Boron uptake by plants increases with decreasing clay content for a given amount of boron added to soil in irrigation or fertilization (Keren et al., 1985a, 1985b). The reason for this is that

TABLE 17.2 Boron Tolerance Limits for Agricultural Crops

	Crop Species	Threshold Concentration	
Boron Tolerance	Name	(mg L ⁻¹)	Slopea
Very sensitive	Lemon	<0.5	
Sensitive	Avocado	0.5-0.75	
	Grapefruit	0.5-0.75	
	Orange	0.5-0.75	
	Grape	0.5-0.75	
	Onion	0.5-0.75	
	Wheat	0.75-1.0	3.3
	Sunflower	0.75-1.0	
	Bean, snap	1.0	12
Moderately sensitive	Broccoli	1.0	1.8
	Radish	1.0	1.4
	Potato	1.0-2.0	
	Lettuce	1.3	1.7
Moderately tolerant	Barley	3.4	4.4
	Corn	2.0-4.0	
	Cauliflower	4.0	1.9
Tolerant	Alfalfa	4.0-6.0	
	Sugar beet	4.9	4.1
	Tomato	5.7	3.4
Very tolerant	Cotton	6.0-10.0	
	Celery	9.8	3.2
	Asparagus	10.0-15.0	

 $^{^{\}rm a}$ % yield reduction resulting from an increase of 1 mg B L^{-1} in the soil solution.

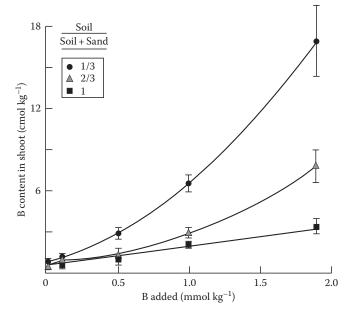

FIGURE 17.7 Relationship between boron content in wheat shoots and the amount of boron added to soil, for three soil-sand mixtures. (Reprinted from Keren, R., F.T. Bingham, and J.D. Rhoades. 1985b. Effect of clay content in soil on boron uptake and yield of wheat. Soil Sci. Soc. Am. J. 49:1466–1470. With permission of the Soil Science Society of America.)

boron absorption increases with increasing clay content as illustrated in Figure 17.7 (Mezuman and Keren, 1981). However, when plant boron content is plotted against boron activity in the soil solution, a linear relationship is obtained (Figure 17.8) indicating that plants obtain their boron solely from that present in the soil solution. Therefore, soil physicochemical characteristics must be taken into consideration when assessing water quality for irrigation in terms of boron. Because adsorption sites may act as a pool from which boron is supplied to solution, adsorbed boron may buffer fluctuations in solution boron concentration, which may change insignificantly by changing the soil water content.

Hanks et al. (1983, 1984) carried out long-term research on the use of saline water ($EC_{iw} = 4 \, dS \, m^{-1}$, boron = 9.4 mg L⁻¹) for irrigation of crops. Over 8 years, no noticeable decrease in yield of forage crops was observed but potato, maize, barley, and wheat yields decreased after the third year mainly due to boron. During the experiment, most of the boron was retained in the soil with levels of 7–10 mg L⁻¹ in saturation extracts. These data demonstrate the need to consider also the composition of saline water when judging its suitability for irrigation. Boron concentrations in irrigation water should not exceed the values in Table 17.2 for the crops indicated. However, salinity likely reduces the effects of boron on plant production (Diaz and Grattan, 2009). Interaction may occur that could increase the individual tolerance coefficient for B and salinity when a crop is exposed to both sources of stress at the same time (Ferreyra et al., 1997).

Chloride and sodium are particularly toxic to fruit trees and woody ornamentals. When the leaves of these plants accumulate more than about 0.5% chloride or 0.25% sodium on a dry weight

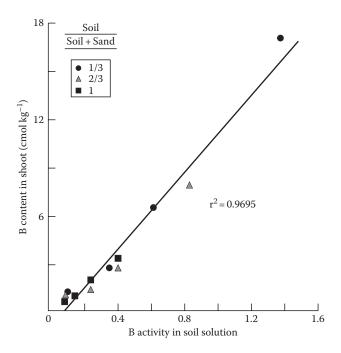

FIGURE 17.8 Relationship between boron content in shoot and the boron activity in soil solution, for three ratios of soil–sand mixtures at a field capacity water content. (Reprinted from Keren, R., F.T. Bingham, and J.D. Rhoades. 1985b. Effect of clay content in soil on boron uptake and yield of wheat. Soil Sci. Soc. Am. J. 49:1466–1470. With permission of the Soil Science Society of America.)

basis, they tend to develop characteristic leaf injury symptoms. Chloride is an essential microelement in very small amounts. Parker et al. (1983) indicated that the decisive attribute appears to be the ability of plants to restrict the transport of Cl⁻ from the root to the shoots. Many woody species are sensitive to chloride ion toxicity, though the degree of sensitivity varies among varieties and rootstocks (Maas, 1990).

High sodium concentrations have been observed to interfere with plant uptake of such essential nutrient element as K or Ca. Tolerance to sodium ion varies widely among species and rootstocks. In the case of avocado, citrus, and stone fruit trees, injury may occur at soil solution concentrations as low as 5 mmol $\rm L^{-1}$. Sodium is adsorbed and retained for a time in the roots and lower trunk, but after some years the sapwood is converted to heartwood and the accumulated sodium ion is released. It is then transported up the canopy, where it may cause leaf scorch (Bernstein, 1975).

17.6 Reclamation of Saline and Boron-Affected Soils

17.6.1 Leaching for Salinity Control

Reclamation of saline soils is essentially a process where soil solution of high salt concentration is displaced by one less concentrated. Consequently, appropriate natural or installed drainage and disposal systems are essential. For flood and sprinkler irrigation, the flow of water is downward, and leaching is defined

with depth. Lateral flow and salt removal from the main root zone typical of drip irrigation can also be considered as temporary leaching. However, rainfall, flood or sprinkler irrigation must be used to occasionally leach out the salt from the entire rooting profile. Leaching efficiency is the amount of salt removed from the root zone in drainage water at a given fraction of the irrigation water. This efficiency depends on salt content and distribution in the soil, solute composition, soil structure, and irrigation method and management.

Soil solution concentration and salt transport mechanisms are the main factors controlling leaching efficiency of noninteracting highly soluble salts. For interacting solutes and less soluble salts, chemical and exchange reactions are also important. For leaching of saline soils, Hoffman (1980) proposed the following empirical equation:

$$\left(\frac{C_{i}}{C_{0}}\right)\left(\frac{D_{i}}{D_{s}}\right) = K \tag{17.35}$$

where

C_i and C₀ are final and initial soil salinities, respectively

D_i and D_s are depth of leaching water applied and depth of soil to be leached, respectively

K is an empirical efficiency parameter that ranges from 0.1 (sandy loam) to 0.3 (clay)

This equation is valid for $D_i/D_s > K$. Relationships between the fraction of initial salt concentration remaining in soil (C/C₀) and depth of leaching water applied per unit depth of soil (D_i/D_s) for continuous and intermittent ponding is presented in Figure 17.9 (Hoffman, 1980). Under continuous ponding, more water is required for leaching the clay loam than sandy loam soil. However, under intermittent ponding, the leaching efficiency of both soils was the same (K = 0.1). Intermittent ponding requires less water than continuous ponding to achieve the same degree of leaching (Miller et al., 1965) and sprinkler irrigation is more efficient than other methods at removing salt from small pores in the soil (Nielsen et al., 1966). Many computer programs are widely available to assess salinity hazard and leaching requirements (LRs). For example, the Extract Chem model version 2.0 is based on the chemical routines used in the UNSTCHEM model (Suarez and Simunek, 1997). The model was developed to predict the major ions and boron concentrations, electrolyte conductivity, and osmotic pressure of a soil solution at a desired water content based on the known ion composition at another water content. The WATSUIT model (USDA, Agricultural Research Service, Riverside, CA) is a computer program that predicts the salinity, sodicity, and toxic-solute concentration of the soil water within a simulated crop root zone resulting from the use of a particular irrigation water of given composition and at a specified LF. This model can be used to evaluate the effect of a given salinity level on crop yield and of a given sodicity level on soil permeability.

Effective irrigation and leaching require uniformity in water application, infiltration, and soil—water-holding capacity. Proper management that integrates irrigation methods and scheduling,

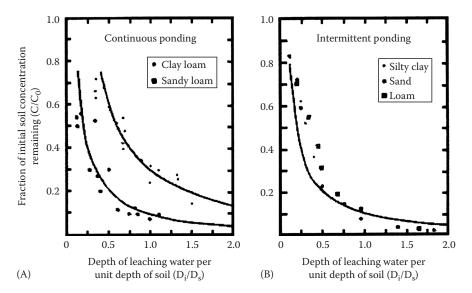

FIGURE 17.9 Relationship between fraction of initial salt concentration remaining in soil and depth of leaching water applied for a given depth of soil. (A) Continuous ponding; and (B) Intermittent ponding. (After Hoffman, G.J. 1980. Guideline for the reclamation of salt-affected soils, p. 49–64. *In* G.A. O'Connor (ed.) 2nd. Inter-Am. Conf. Salin. Water Manag. Tech. NM State University, Las Cruces, NM.)

soil treatments, and special cultivation practices is aimed at improving infiltration uniformity. With flood or furrow irrigation, land leveling, increased watering rates, and soil treatments that improve infiltration are recommended practices. Improvement of infiltration uniformity is obtained by reducing application rates below the soil infiltration capacity, addition of ameliorating chemicals that control crust formation, and use of cultivation practices that increase surface storage and reduce local and long distance runoff, such as check dams in the furrow or rough surface disking.

Furrow or drip irrigation leaches salt below and away from the infiltrating areas but salt accumulates at lateral wetting fronts, most commonly in bed ridges, and at the soil surface between emitters. Long-term use of drip irrigation may result in irregularly distributed salt accumulations, such that may affect crops to be planted in subsequent years. Special cultivation practices that carry salts away from the planting position or adjust planting position to salt distribution in the topsoil are essential (Ayers and Westcot, 1985). With both furrow and drip, occasional leaching by rain, flood or sprinkler irrigation is required to remove salt from the entire root zone.

When fields contain several soil types, leaching is more efficient in sandy than clay-rich portions. If leaching is continued until the clay-rich portions are sufficiently leached, an excessive amount of water would have percolated through the sandy areas. This problem is pronounced under ponded leaching where sandy areas are preferentially leached. In fact, the distribution of salinity in basin, border, or furrow-irrigated fields coincides closely with soil type (Miyamoto and Cruz, 1986, 1987). To increase efficiency, leaching should be based on the distribution of soil types (Miyamoto and Cruz, 1986) or the use of stochastic analysis of solute transport in spatially variable fields to divide a field into small sections that need different amounts of water (Russo, 1984). Dividing highly variable fields into areas of uniform soil type, with irrigation

varying according to moisture-holding capacity and infiltration of each area, can significantly increase leaching efficiency.

When salts accumulate in the root zone during the irrigation season, they can be leached by applying water above the amount needed for ET. Over time, salt removal by leaching must equal or exceed salt additions from the applied water. To calculate the LR, both the irrigation water quality and the crop tolerance to soil salinity must be known (Ayers and Westcot, 1985).

Large changes in soil salinity under nonsteady-state conditions arise from rainfall during and out of the irrigation season, changes in irrigation water quality for significant periods, and heavy intermittent leaching rather than a constant LF at every irrigation. If management can synchronize changes in soil salinity with crop tolerance at different growth stages, the use of brackish water may be increased without detriment. When rainfall can accomplish the required leaching without stressing the crop, additional leaching is not required. This may be the case with tolerant crops in humid climates, or during wet years in semiarid zones. With sensitive crops in humid climates and tolerant crops during dry years in semiarid and arid zones, additional leaching by irrigation may be required.

Leaching into tile or open ditch drains rapidly removes salt directly above and near the drains but removes little midway between the drains. Leaching efficiency decreases as soon as the rapid flow reaches the drains. This uneven leaching is more evident in water-saturated (Luthin et al., 1969) than unsaturated fields, where leaching above the water table is a one-dimensional process (Talsma, 1967). To leach more efficiently, it is necessary to avoid ponding water near the drains (Miyamoto and Warrick, 1974) and apply water intermittently to keep the water table as low as possible (Talsma, 1967).

The high salt–water dilution technique (Reeve and Bower, 1960), which involves successive dilutions of a very saline irrigation water containing divalent cations, can be used when (1) the soil

physical conditions have deteriorated and HC of the soil is so low that the time required for reclamation or the amount of amendment required is excessive, or (2) if a sodic soil is to be leached with a water so low in salinity that water infiltration decreases adversely. A nomograph is available for predicting reclamation at various stages of leaching (Reeve and Doering, 1966a). In the early phase, the high salinity of the water prevents clay dispersion and promotes flocculation, and the Ca content provides a source of Ca to replace exchangeable Na so that sodicity is decreased. On dilution with high quality water, the SAR of the irrigation water is reduced by the square root of the dilution factor. To ensure reclamation to the desired depth, D_i/D_o should be about 9 (Reeve and Doering, 1966a). This method is particularly effective for soils with swelling clays that have extremely low HC. A theoretical analysis of the use of high salt water in reclaiming sodic soils by the addition of a constant quantity of Ca2+ in every step in successive dilutions is presented by Misopolinos (1985).

In the reclamation of a highly sodic clay loam soil, Reeve and Doering (1966b) found that IR for a saturation gypsum solution was only 2 \times 10⁻⁸ m s⁻¹ and the time for reclamation to 0.9 m was 7 years of continuous leaching. However, the profile was reclaimed in 3 days with a series of CaCl₂ solutions (300 to 6 mol m⁻³). The average IR for the CaCl₂ solutions was about 150 times that for the gypsum solution. This method has also been shown to reclaim a slowly permeable sodic soil in a humid environment, where HC and IR were increased from 30% to over 100% (Rahman et al., 1974).

The successful application of this method requires a balance between maintaining high EC to reduce reclamation time and low EC to reduce the amount of amendment required. A practical technique is to apply only two-thirds of the solution depth required for exchange equilibria with three dilutions of CaCl_2 followed by a gypsum application to satisfy the remaining exchange requirement, and completed by leaching with 0.3 m water m^{-1} soil to be reclaimed. This final step is essential to leach the saline solutions below the root zone.

Leaching reclamation without amendments (Jury et al., 1979, 1987) can be successful when soil drainage is good, adequate leaching water is available, and an internal source of Ca exists (e.g., CaCO₃). The rate at which CaCO₃ dissolves in water depends on the surface area-solution volume ratio, ionic composition of the solution and solid phases, clay affinity for cations, temperature, and P_{CO2}. Amrhein et al. (1985) concluded that transfer of atmospheric CO2 to solution is an important ratelimiting step in the dissolution kinetics of CaCO₃ in soils. The ion activity product (IAP) values expected for calcite (Suarez and Rhoades, 1982) are obtained for CaCO₃ particles, isolated from the soils, and in water. On the contrary, a supersaturation with respect to calcite that was observed in solution extracts from calcareous soils (Levy, 1981) appears to be due to the presence of silicates more soluble than calcite, and is not the result of unstable CaCO₃ phases (Suarez and Rhoades, 1982). Plummer et al. (1979) concluded that there are several uncertainties in modeling the kinetics of carbonate chemistry; at low pH, the rate depends significantly on the thermodynamic transport constant for H⁺, which is not well defined, while reaction site density and controls on pH at the interface between the crystal and the bulk solution are also not well understood.

Soil CaCO₃ may dissolve slowly to contribute Ca, especially in the reclamation of saline sodic soils in which its solubility is enhanced (Oster, 1982). Sodic soils commonly contain CaCO₃ that dissolves and maintains the soil solution concentration levels above the flocculation value of the soil clays (Alperovitch et al., 1981). This, in turn, reduces ESP and prevents HC from decreasing when exposed to rain. On the other hand, addition of CaCO3 to nonsaline sodic soils is of doubtful value because its dissolution rate is too slow to provide sufficient Ca for exchange, unless an acid or acid former is applied concurrently. Calcareous soils with moderate ESP levels maintain reasonable physical properties through most of the profile but remain susceptible to dispersion near the surface because EC near the surface may be insufficient to maintain physical structure during raindrop impact (Keren, 1991). Under such conditions, an application of a soil amendment (gypsum) on soil surface is necessary to keep IR sufficiently high (Keren and Shainberg, 1981).

17.6.2 Leaching for Boron Control

Boron can be effectively leached from soil although the rate of removal is much slower for boron than for Cl^- or $\text{SO}_4{}^{2^-}$ salts (Bingham et al., 1972). Griffin and Burau (1974) studied the kinetics of boron desorption from soils and observed two pseudo-first-order reactions and a very slow reaction. They speculated that the fast reactions were due to desorption from hydroxy-Fe, -Mg, and -AI materials in the clay size fraction, whereas the slowest reaction rate was due to diffusion of boron from the interior of clay minerals to the solution phase.

The presence of excess soluble boron in many arid soils is usually attributed to the application of boron-containing irrigation waters or the weathering of boron-containing materials. Adsorption/desorption of boron controls its removal from soils. Griffin and Burau (1974) showed that desorption (Figure 17.10)

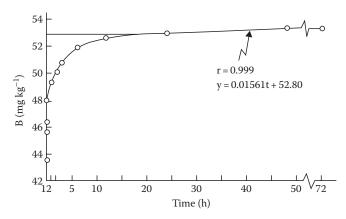

FIGURE 17.10 Solution boron concentration in leachate from soil, naturally high in boron, as a function of time. (Reprinted from Griffin, R.A., and R.G. Burau. 1974. Kinetic and equilibrium studies of boron desorption from soil. Soil Sci. Soc. Am. J. 38:892–897. With permission of the Soil Science Society of America.)

was largely from relatively fast reactions on hydroxy-Fe, Mg, and Al materials in the clay fraction, which are independent of soil texture and initial soil boron content. The slowest reaction rate was due to boron diffusion from the interior of clay minerals to the solution phase. They did not consider the role of clay minerals and primary boron minerals in its desorption and dissolution processes.

If excessive amounts of boron accumulate in soils, reclamation can be accomplished by extensive leaching. Leaching experiments (Reeve et al., 1955; Rhoades et al., 1970; Bingham et al., 1972) show that a large fraction of soil boron can be removed by percolating waters but that the remainder persists even after large amounts of water have been applied. The volume of low boron water needed to reduce it from toxic to nontoxic levels is two- to threefold greater than is needed for a comparable reduction in Cl (Reeve et al., 1955; Bingham et al., 1972).

The relative decrease in soluble boron in field soils during reclamation is given by (Hoffman, 1980)

$$\left(\frac{C}{C_0}\right)\left(\frac{D}{D_s}\right) = 0.6\tag{17.36}$$

where

C and C_0 are the final and initial soluble boron concentrations D/D_c is the depth of leaching water per unit depth of soil

Equation 17.36 is independent of the method of water application (sprinkler or ponding).

Since extensive leaching is required for reclaiming soils with excessive boron, the reclamation should be pursued while tolerant crops are cultivated; and then when boron levels have been reduced, more sensitive crops can be cultivated. Alternatively, high boron soils can be reclaimed by adding amendments such as $\rm H_2SO_4$. Because boron adsorption is pH dependent (Keren and Bingham, 1985), acidification effectively increases the boron concentration in soil solution thereby making leaching more effective (Prather, 1977). Furthermore, as Si concentration increases with decreasing pH to levels higher than those of boron, Si can compete for adsorption sites (Bingham and Page, 1971; McPhail et al., 1972). During leaching, the presence of Si may decrease readsorption of boron or even cause boron desorption. Applying $\sim 3 \, {\rm Mg} \, {\rm H_2SO_4} \, {\rm ha^{-1}}$ reduced the amount of water needed to leach the same amount of boron fivefold (Prather, 1977).

Lime-induced boron deficiency has frequently been observed in acid soils, and is probably due to increased boron adsorption resulting from the increased pH and not a direct effect of Ca per se (Hatcher and Bower, 1967). In acid soils, increasing rates of boron lowered yield and caused increasing typical boron toxicity symptoms (Bartlett and Picarelli, 1973). However, in the presence of lime, boron toxicity was prevented as soil pH increased above 6.

Native soil boron is more difficult to leach than boron accumulated from previous irrigations. The reduced boron concentrations that follow the leaching of native high boron soils may be temporary. Increasing storage times of water in the soil

profile results in larger increases in effluent boron concentrations (Rhoades et al., 1970; Bingham et al., 1972). Peryea et al. (1985) showed that this phenomenon, termed boron regeneration, is inversely related to the amount of water used for the initial leaching. Boron regeneration is, therefore, of primary concern during the early stages of soil reclamation, when appreciable residual sources of regenerable boron are present. The potential for reestablishing phytotoxic concentrations in a soil is a function of the relative completeness of the reclamation processes and the rate of boron dissolution after reclamation.

18.1 Introduction

Soils in numerous areas of the world are adversely affected by the presence of excess Na in the soil solution and as an exchangeable cation. For example, it is estimated that ~50% of the arable land in Australia suffers from sodicity-related problems (Naidu, 1993). Sodium-affected soils exhibit poor soil water and air relations that adversely affect water movement in the soil, root growth, and plant production, and make the soil difficult to farm when either dry or wet. Consequently, in many cases, such soils have had to be abandoned.

Sodium-affected soils have been referred to in the past as alkali soils. This may have originated from the traditional separation of salt-affected soils into two groups (Szabolcs, 1979): (1) saline soils (soils affected by neutral Na salts, mainly NaCl and Na₂SO₄) and (2) alkali soils (soils affected by Na salts capable of alkaline hydrolysis, including NaHCO₃, Na₂CO₃, and Na₂SiO₃). However, at present, Na-affected soils are referred to as sodic soils, with the realization that the level of Na in the soil solution and on the exchange complex, in conjunction with the total electrolyte concentration (TEC), determines whether or not a given soil is sodic, and not the type of the Na salt.

Problems associated with sodic soils have long been recognized (e.g., special issue of Australian Journal of Soil

Research [vol. 31 no. 6], 1993; Sumner and Naidu, 1998) and are, unfortunately, expected to increase in the future. The ever increasing need to provide food to an expanding worldwide population, coupled with the increasing demand for good quality water from urban and industrial sectors, results in poorer quality water and soils being used for food production. Wastewater, whether drainage or recycled municipal water, being significantly more saline and sodic than fresh water, is rapidly becoming a common source of water for agriculture in many areas in the world. Consequently, understanding sodic soil behavior and its effects on agriculture and the environment is essential in order to properly manage sodic soils for crop production and sustainable agriculture in many parts of the world. This chapter provides, therefore, a general review of various aspects related specifically to sodic conditions in soils.

18.2 Sodic Soils: Definition and Distribution

18.2.1 Definition of Sodic Soils

Prior to defining sodic soils it is necessary to define the parameters by which sodicity is evaluated. Two important parameters are generally used. The first is the exchangeable sodium percentage (ESP) that describes the fraction of adsorbed Na from the cation exchange capacity (CEC) of the soil, and is defined as

$$ESP = 100(Exchangeable Na/CEC)$$
 (18.1)

where the CEC is normally determined at a reference pH (7.0 or 8.2). The second parameter reflects the sodicity level of the irrigation water or soil solution and is termed the sodium adsorption ratio (SAR) defined as

$$SAR = \frac{[Na]}{([Ca + Mg]/2)^{0.5}}$$
 (18.2)

where brackets [] reflect cation concentrations in mmol_c L^{-1} . Thus, SAR has units of (mmol_c L^{-1})^{0.5}. It should be emphasized that the sodicity hazard of solutions is related to the ratio of Na to the divalent cations present in the water and not to Na concentration alone. A more accurate calculation of the SAR is obtained when cation activities are used instead of cation concentrations. Additionally, Sposito and Mattigod (1977) introduced corrections for cation concentrations due to ion pairs or complexes and arrived at the following empirical relation between true (SAR_t) and measured (SAR_p) SARs:

$$SAR_{t} = 0.08 + 1.15SAR_{p}$$
 (18.3)

Furthermore, in arid and semiarid soils, irrigation may lead to dissolution/precipitation of $CaCO_3$, depending on the pH and the CO_2 partial pressure (pCO $_2$) of the system. Thus, the SAR of the irrigation water (SAR $_{iw}$) may differ from the SAR of the drainage water (SAR $_{dw}$), with the latter being considered as a better indicator for sodicity hazard. Bower et al. (1968) proposed the use of SAR $_{iw}$, pH, and leaching fraction for calculating SAR $_{dw}$ (also known as SAR $_{adj}$). Rhoades (1968) added to this relationship the contribution of mineral dissolution. Later, Suarez (1981) suggested that SAR $_{dw}$ be calculated based on the concentration of Na and Mg in the irrigation water, leaching fraction, and pCO $_2$. The equation proposed by Suarez (1981) is considered more accurate and easier to use than other equations for calculating SAR in the soil and drainage water (Frenkel, 1984).

Exchange reactions take place between the soil solution and the exchange phase. Thus, soil ESP can be estimated from the SAR of saturated paste extracts using the following empirical relationship (USSL Staff, 1954):

$$ESP = 100(-0.0126 + 0.01475SAR)/(1+[-0.0126 + 0.01475SAR])$$
(18.4)

or from the nomograph presented in Figure 18.1. When more dilute extracts are used, such as 1:5 soil:water ratio, then a different relationship holds (Rengasamy et al., 1984):

$$ESP = 1.95 SAR + 1.8$$
 (18.5)

The USSL Staff (1954) empirical method has been developed using 59 soil samples from 9 western states of the United States.

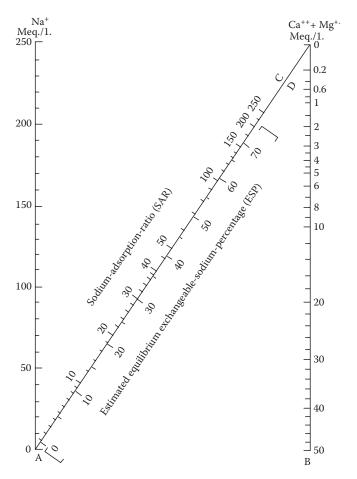

FIGURE 18.1 Nomograph for determining the SAR of a saturation extract and estimating the corresponding ESP value of the soil at equilibrium with the extract. (Courtesy of USSL Staff. 1954. Diagnosis and Improvement of saline and alkali soils. Agricultural Handbook No. 60. USDA, Washington, DC.)

Nevertheless, it has gained worldwide popularity because of its simplicity and has been extensively used to predict the ESPs of Na affected soils, even in recent years (e.g., Condom et al., 1999; Faulkner et al., 2001; Chhabra, 2005).

The use of the USSL Staff (1954) empirical SAR-ESP relation can, at times, lead to erroneous estimation of soil ESP. Ganjegunte and Vance (2006) noted for five sites in Wyoming that the ESP determined by using NH₄OAc was lower than the ESP estimated using the SAR-ESP empirical relationship provided by the USSL Staff (1954). Furthermore, Kopittke et al. (2006) observed that clays in which external exchange sites dominate (kaolinite and pyrophyllite) tend to show an overall preference for Na. In the case of illite (2:1 nonexpanding mineral), the clay displayed an overall preference for Ca. For the expanding 2:1 clay, montmorillonite, Na-Ca exchange varied with ionic strength; at low ionic strength and high ESP, the clay platelets displayed preference for Na. However, as ionic strength increased and ESP decreased, preference for Ca increased. Kopittke et al. (2006) concluded that the relationship between SAR and ESP is not constant and should be determined directly for the soil of interest.

To date there is no widely accepted definition of a sodic soil. The USSL Staff (1954) defined sodic soils as those whose physical properties are adversely affected by the presence of Na and suggested that ESP of 15 should separate sodic from nonsodic soils. The USSL Staff (1954) added the reservation that this limit must be regarded as somewhat arbitrary and tentative. The study of McNeal and Coleman (1966), who used seven soils from the western United States, supported the conclusion that ESP 15 can separate between sodic and nonsodic behavior of the soil; however, it was added that the electrolyte concentration in the percolating solution must exceed 3 mmol_c L⁻¹ in order for this to hold true. Greene et al. (1978) suggested that the threshold value separating sodic from nonsodic soils should depend on soil texture; they proposed ESPs of 10 and 20 for fine and coarse textured soils, respectively. In Australia, McIntyre (1979), who used water with TEC of 0.7 mmol_c L⁻¹, proposed that soils with ESP > 5 should be considered as Na-affected (sodic) soils. More recent hydraulic conductivity studies by Mace and Amrhein (2001) and Levy et al. (2005) with calcareous semiarid soils supported the suggestion of McIntyre (1979) that ESP > 5 already imparts a sodic behavior. The differences in the proposed critical ESP levels separating sodic from nonsodic soils could arise, in part, from the fact that in California (USSL Staff, 1954) water with a TEC of >2 mmol_c L⁻¹ was being considered, whereas in Australia (McIntyre, 1979), the TEC of the water under consideration was only 0.7 mmol_c L⁻¹. Consequently, a much higher ESP was required before degradation of the soil in the California studies was observed. The above critical ESP levels were determined based on hydraulic conductivity (HC) measurements but studies on soil susceptibility to aggregate slaking (Levy et al., 2003), seal formation, runoff, and soil loss (Agassi et al., 1981; Kazman et al., 1983; Mamedov et al., 2002; Tang et al., 2006) have revealed that soils can exhibit a sodic behavior even at ESPs of 2-4. In view of the continuous effect of Na on soil behavior, from low to high ESP and TEC levels, no satisfactory decision or a critical level of ESP can be made. However, as will be shown later, the interrelationship between the ESP of the soil or the SAR of its equilibrium solution, and the TEC of the soil solution is important in dictating whether a sodic or a nonsodic behavior will be observed. Oster and Jayawardane (1998) present an example for this approach with the assessment of the permeability hazard of infiltrating waters having different TEC values when applied to soils with SAR values in the range of 0-60 (Figure 18.2).

18.2.2 Distribution of Sodic Soils

Before considering the world distribution of sodic soils, it should be pointed out that, for most sodic soils, sodicity is a natural phenomenon related to the nature of the parent material and subsequent pedogenic processes. However, there are also sodic soils where sodicity arises from anthropogenic processes, and is thus termed secondary sodification. Irrigation without proper drainage, forest clearing, and other land management practices

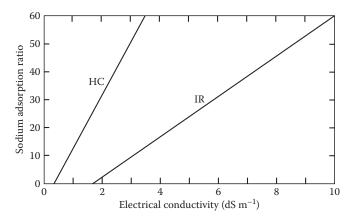

FIGURE 18.2 Threshold values of sodium adsorption ratio and electrical conductivity for hydraulic conductivity (HC) and infiltration rate (IR) levels associated with the likelihood of substantial losses in permeability. (From Oster, J.D., and N.S. Jayawardane. 1998. Agricultural management of sodic soils, p. 143–165. *In* M.E. Sumner and R. Naidu (eds.) Sodic soils. Oxford University Press, New York. With permission.)

that can lead to waterlogging, are the main human activities that yield rapid secondary sodification (Rengasamy and Olssen, 1991; Fitzpatrick et al., 1994). It is expected that secondary sodification of soils will increase considerably in the future, because of the growing use of poorer quality waters and soils for food production to meet the demand of the growing population, and the need to reuse drainage water to compensate for the increasing shortage of good quality water for irrigation.

Sodic soils cover 580 million ha worldwide (Szabolcs, 1989); the areas of sodic soils on each continent and in regions where they form an important proportion of the total area are presented in Table 18.1. The largest areas of sodic soils are concentrated in Australia and north-central Asia. In Australia, it is estimated that 25%–30% of the area is occupied by sodic soils with widespread occurrence (Northcote and Skene, 1972). In North America, many of the sodic soils occur on the Great Plains of western Canada and the northern United States, under cold, semiarid to subhumid climates (FAO,

1991). In South America, sodic soils are concentrated in the Argentinian and Paraguayan pampas and northeastern Brazil (FAO, 1991) while in Europe, they occur in the Carpathian basin, Hungary (Trans-Tisza region and the Danube-Tisza interfulve), Romania, Serbia, Slovakia, Ukraine (near the Black Sea), and the Transcaucasian plain of Georgia and Azerbaijan (Bui et al., 1998). In northern and central Asia, sodic soils are concentrated mainly (1) west of the Caspian Sea in Kazakhstan, Turkmenia, Uzbekistan, Tadzhikistan, and Kyrghizia (FAO, 1978); (2) south of the Tien Shan Mountains in the basin of the Xinjiang-Gansu-Qinghai provinces, on the Huang and Huari river plains and in northeastern Manchuria, China; (3) in the Russian Republic of Yakutia; and (4) in the forest-meadowsteppe region of western Siberia (Bui et al., 1998). In southern Asia and the Middle East, sodic soils are widespread and can be found in India, Syria, Iran, Pakistan, and Bangladesh (Bui et al., 1998). In Africa, sodic soils occupy only 0.9% of the total land area and are concentrated in the Kalahari Basin, coastal Tunisia, Chad, Nigeria, Somalia, Sudan, Tanzania, and southern Africa (Bui et al., 1998).

The spatial distribution of sodic soils demonstrates that they occur under a range of climates. Among the environmental conditions that promote the formation of sodic soils are the presence of shallow saline groundwater, the occurrence of perched water tables within 1 m of the soil surface, impeded drainage, low slope gradients, and textural discontinuities during deposition of sediments such as eolian, glacial, or alluvial materials (Bui et al., 1998).

The outlined distribution of sodic soils and the conditions promoting their formation are based on a pedological or morphological approach. By contrast, a more useful definition of sodic soils is based on land management considerations (Section 18.2.1). Many agricultural soils that exhibit sodic behavior may not fit into the classical sodic soil group, because typical morphological features including columnar subsurface structure are not present. Consequently, the large areas that these soils cover remain largely undetermined.

18.3 Processes Characterizing the Behavior of Sodic Soils

18.3.1 Clay Charge and the Diffuse Double Layer

Interaction between solid and solution phases plays a dominant role in determining physical behavior of soil. Of the various soil constituents, colloidal clay determines much of the physical behavior of soils because of its large specific surface area and charge, which makes it very reactive in physicochemical processes such as swelling and dispersion. These two processes determine, to a large extent, soil microstructure and thus many of its physical properties. A complete discussion of the processes involved in clay dispersion and swelling is presented in Chapter 15 of *Handbook of Soil Sciences: Properties and Processes*.

18.3.2 Swelling and Dispersion

18.3.2.1 Reference Clay Systems

Upon wetting, swelling takes place in smectites represented most commonly in soils by the mineral montmorillonite. Repulsion forces (swelling pressure) that can be predicted from the diffuse double layer (DDL) theory are responsible for the swelling (van Olphen, 1977; Bresler et al., 1982). When saturated with Na ions and in the presence of a dilute solution, a diffused (wide) DDL forms creating high swelling pressures between the clay platelets, resulting ultimately in dispersion of the platelets (Banin and Lahav, 1968; Shainberg et al., 1971). Conversely, low swelling pressures are observed between Ca-saturated platelets because strong electrical attraction forces between Ca and the clay surfaces (not considered by the DDL theory) prevent complete swelling of Ca montmorillonite, even in distilled water (DW). Instead, Ca platelets aggregate into tactoids or quasicrystals consisting of four to nine platelets each (Aylmore and Quirk, 1959; Blackmore and Miller, 1961) with DDL formation only on the outer and not the internal surfaces of the tactoids (Blackmore and Miller, 1961), which results in a much smaller effective surface area than actually present.

In mixed Na–Ca systems, the ions are not randomly distributed throughout the system as was previously thought (Bresler, 1970), with Ca and Na being located preferentially on inner and outer surfaces, respectively (McAtee, 1961; Shainberg and Otoh, 1968; Bar On et al., 1970; Shainberg et al., 1971). This phenomenon is called ion demixing (Figure 18.3). Shainberg et al. (1971) demonstrated that clay swelling is limited at ESP < 15 because of

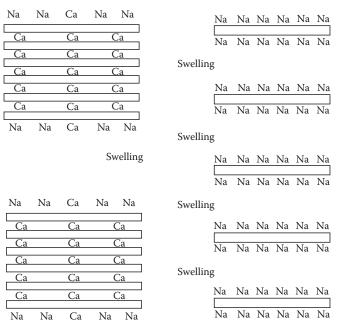

FIGURE 18.3 Comparison of particle arrangements in a homoionic Na montmorillonite (right) with that in a Na–Ca system (left) illustrating the formation of tactoids or quasicrystals with demixing of Na and Ca. (Reprinted from Sumner, M.E. 1993. Sodic soils: New perspectives. Aust. J. Soil Res. 31:683–750.)

demixing; as ESP increases further, a sharp increase in macroscopic swelling occurs as Na enters the tactoids, and at ESP > 50, swelling in mixed Na–Ca and pure Na systems is similar.

In a stable clay suspension, particles frequently collide because of Brownian motion, but separate again because of DDL repulsive forces. When TEC or valency of the counter ions is increased, DDL forces are reduced, allowing particles to remain together after collision to form flocs that subsequently settle. The minimum TEC at which this occurs is called the critical floculation concentration (CFC), or simply the flocculation value (FV). For Na and Ca montmorillonite, CFCs are 7–20 mmol_c L⁻¹ NaCl and 0.25–1.09 mmol_c L⁻¹ CaCl₂, respectively (Goldberg and Glaubig, 1987). Increasing pH from 4 to 10 has only a small effect on the CFC of Na montmorillonite, but addition of humic substances causes a marked increase over the pH range 4–8 (Tarchitzky et al., 1993).

For Na and Ca illite, CFC values are $40-50\,\mathrm{mmol_c}$ L⁻¹ NaCl and $0.25\,\mathrm{mmol_c}$ L⁻¹ CaCl₂, respectively (Arora and Coleman, 1979). At low ESP levels, the CFC of illite is higher than that of montmorillonite because of the smaller attractive forces in illite; illite surfaces are terraced, which leads to mismatching and subsequent poor contact so that the particles cannot approach each other as closely (Oster et al., 1980).

Kaolinite saturated with Na remains flocculated in a salt-free solution at pH < 7 because the positively charged edges interact with the negative basal planes (Schofield and Samson, 1954). Elimination of edge positive charge by increasing the pH, addition of small amounts of various salts such as sodium oxalate, sodium pyrophosphate, sodium polymetaphosphate, and sodium alginate (Schofield and Samson, 1954; Durgin and Chaney, 1984; Frenkel et al., 1992), or introducing small impurities of montmorillonite or illite to the kaolinite suspension (Frenkel et al., 1978; Chiang et al., 1987) brings about dispersion (Goldberg and Forster, 1990). Consequently, kaolinite systems cannot be represented by a unique CFC.

A distinction should be made between swelling and dispersion even though both result from the balance between DDL repulsive forces and van der Waals attractive forces. Swelling is a continuous and reversible process, whose magnitude depends on the TEC of the ambient solution and the degree of sodicity. Dispersion is not continuous and may occur even at low ESP levels as long as the TEC < CFC. Dispersion is an irreversible process because flocculation by increasing TEC does not result in the original particle associations and orientations.

18.3.2.2 Soil Clay Systems

At low ESP levels, dispersion rather than swelling is the main mechanism for physical degradation of soils. Only when ESP > 15, is the role of swelling dominant in determining soil physical properties (Shainberg and Letey, 1984).

Flocculation and dispersion behavior of soil clays differs significantly from that of pure clay systems, because they usually occur as mixtures and complexes with other minerals, oxides, and soil organic matter (SOM). Goldberg and Forster (1990) and Frenkel et al. (1992) demonstrated that the CFC values of

soil clays are 2- to 10-fold higher than for pure clay systems. Conversely, in the presence of hydrous oxides (McNeal et al., 1968) or sparingly soluble minerals such as CaCO₃ (Shainberg et al., 1981a, 1981b), clay dispersivity is much less severe. Hence, extrapolation from pure clay to soil systems is extremely difficult. Goldberg and Forster (1990) demonstrated that the smallest differences in CFC were found between reference and soil illites, indicating that in many dispersive soils that contain illite or weathered mica (Rengasamy et al., 1984; Miller and Baharuddin, 1986; Miller et al., 1990), illite plays an important role in their dispersibility.

Clay dispersion is affected not only by the presence of Na but also by the type of complementary divalent cation. The presence of Mg enhances clay dispersion in soils with mixed mineralogy (Ali et al., 1987; Yousaf et al., 1987), as well as in kaolinitic (Emerson and Smith, 1970) and illitic (Rengasamy et al., 1986) soils, compared to Ca. Furthermore, aggregates saturated with Na and Mg disperse at lower ESPs than those saturated with Na and Ca (Emerson and Bakker, 1973; Ali et al., 1987).

Disintegration of aggregates on wetting and subsequent dispersion of clay from the aggregates cannot be adequately explained by the classical theory of DDL repulsive and van der Waals attractive forces developed for colloidal systems. Rengasamy and Sumner (1998) proposed a schematic model to explain swelling and dispersion of soil clay particles when dry aggregates are wetted (Figure 18.4). Initially, hydration of the adsorbed cations leads to swelling, further hydration of highly sodic soils results in spontaneous dispersion, while mechanical stresses (raindrop impact, tillage, etc.) lead to dispersion even of soils containing predominantly divalent cations. Dehydration of the aggregates and the buildup of an osmotic pressure by increasing the TEC leads to flocculation of the dispersed particles once more (Rengasamy and Sumner, 1998).

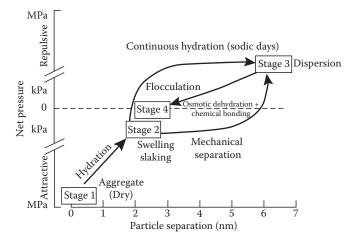

FIGURE 18.4 Schematic illustration of processes that take place and intensity of attractive and repulsive forces involved when a dry aggregate of a soil is wetted. (Reprinted from Rengasamy, P., and M.E. Sumner. 1998. Processes involved in sodic behavior, p. 51–67. *In* M.E. Sumner and R. Naidu (eds.) Sodic soils. Oxford University Press, New York. Copyright Oxford University Press, New York. With permission.)

18.4 Aggregate Stability and Organic Matter in Sodic Soils

18.4.1 Aggregation and Its Importance

Aggregation in soils is the arrangement of primary particles (sand, silt, and clay) into secondary structural units, typically on a millimeter scale. Soil aggregates thus consist of clay particles, in quasicrystals or domains (Quirk and Aylmore, 1971), interspersed with larger quartzitic primary particles and held together by physicochemical forces that are a product of the chemical and microbiological environment of that particular soil.

Recalling Bradfield's early statement that "granulation is flocculation plus," Quirk (1978) emphasized that a necessary condition for the formation of water-stable granules is clay flocculation, followed by stabilization by organic and/or inorganic cementing agents. The principles of flocculation and dispersion are central to the formation of clay quasicrystals and floccules (<20 µm) that become the building blocks of aggregates. Such floccules are further aggregated by inorganic (clay particles or metal oxides) or organic (humified or residual microbial products) materials into microaggregates, ranging from 20 to 250 µm in size. Macroaggregates, typically >250 µm, are agglomerates containing microaggregates plus primary sand and silt particles, held together largely by root hairs, fungal hyphae, and large biomolecules (Tisdall and Oades, 1982). The picture in Figure 18.5, modified from a diagram of Greenland (1979), illustrates these constituents and associations. A further discussion of the role of SOM in structure development is given in Section 18.4.3.

Aggregate breakdown by water may result from a variety of physical and physicochemical mechanisms. Four main mechanisms have been identified: (1) slaking, that is, breakdown caused

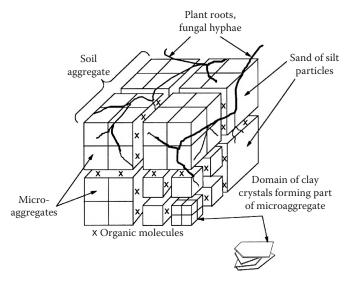

FIGURE 18.5 Heirarchial structure of aggregates. (Adapted from Greenland, D.J. 1979. Structural organization of soils and crop production, p. 47–56. *In* R. Lal and D.J. Greenland (eds.) Soil physical properties and crop production in the tropics. John Wiley & Sons, New York. Copyright John Wiley & Sons, New York. With permission.)

by compression of entrapped air during fast wetting (Panabokke and Quirk, 1957), (2) breakdown by differential swelling during fast wetting (Kheyrabi and Monnier, 1968), (3) breakdown by impact of raindrops (McIntyre, 1958), and (4) physicochemical dispersion due to osmotic stress upon wetting with low electrolyte water (Emerson, 1967). These mechanisms differ in the type of energy involved in aggregate disruption. For instance, swelling can overcome attractive pressures in the magnitude of mega-Pascals (Rengasamy and Olssen, 1991) while slaking and impact of raindrops can overcome attractive pressures in the range of kilo-Pascals only (Rengasamy and Sumner, 1998). In addition, the various mechanisms may differ in the size distribution of the disrupted products (Farres, 1980; Chan and Mullins, 1994) and in type of soil properties affecting the mechanism (Le Bissonnais, 1996). Regarding the latter, slaking may be affected by porosity and internal cohesion while physicochemical dispersion will be affected by clay mineralogy, ionic composition, and concentration.

18.4.2 Sodicity Effects on Aggregate Stability

The effect of exchangeable Na in inhibiting macroaggregation (i.e., enhancing aggregate breakdown) may occur by weakening the covalent associations between organic materials and soil minerals, and/or by increasing the osmotic/hydration forces that can cause particle repulsion during wetting.

Direct measurements of the effects of sodicity on aggregate stability have yielded inconclusive results. Some studies covering a wide range of soil texture (Coughlan and Loch, 1984; Goldberg et al., 1988; Chappell et al., 1999) observed no correlation between aggregate stability and level of ESP. Other studies, however, have suggested that macroaggregate slaking was affected by fractional Na coverage only in the range of ESP > 5 (Aly and Letey, 1990) or ESP > 10 (Shainberg et al., 1992). Crescimanno et al. (1995) noted for two clay soils that aggregate stability decreased linearly with an increase in ESP in the range of 2–15. Levy and Mamedov (2002) and Levy et al. (2003) noted that ESP \leq 6 could already have an adverse effect on aggregate stability, especially in fine-textured soils.

Levy et al. (1993) reported that the stability of 105 µm microaggregates was affected by increasing ESP from 1 to 25 and that increasing sodicity had a similar effect on both aggregate breakdown and clay dispersion. They concluded that dispersion is the driving force controlling breakdown of microaggregates at high ESP. Conversely, Abu-Sharar et al. (1987a, 1987b) showed for soils from California that in soils with a high proportion of macropores, sodic conditions (SAR 10) enhance aggregate slaking and that this process was independent of clay dispersion.

Rengasamy et al. (1984) made a distinction between spontaneous dispersion (i.e., slaking) where aggregates in suspension are not physically disturbed, and mechanical dispersion where aggregates are shaken in water. High ESP (>10) and low TEC values are needed for spontaneous dispersion. Under mechanical stress (e.g., impact of raindrops, shear force of flowing water,

mechanical energy of cultivation machinery), aggregate break-down and clay dispersion are observed even at low ESP (<10) levels (Shainberg et al., 1992). However, in the presence of Al and Fe oxides, high ESP and low TEC have only a small effect in promoting aggregate breakdown and clay dispersion (McNeal et al., 1968; El-Swaify, 1973).

18.4.3 Organic Matter Effects in Sodic Soils

Organic matter comprises about 1%–10% of a typical soil's mass of which 1%–5% is microbial biomass (Nelson and Oades, 1998). Organic matter acts both as a bonding and dispersing agent in soils. The balance between these opposing effects depends upon the nature of the organic materials and their types of interaction with inorganic colloids. With respect to its effects on soil structure and aggregate stability, SOM can be divided into transient and persistent bonding agents.

Transient components of SOM include plant roots and fungal hyphae. They enmesh macroaggregates (Figure 18.5) and inhibit aggregate breakdown. Transient components are so named because they are present only when plants are growing and fresh organic matter is added, and because they are readily disrupted by some mechanical disturbance (Nelson and Oades, 1998). Soil stability, and especially that of macroaggregates, has often been related to the presence of transient binding agents in soil (Emerson, 1954; Loveland et al., 1987; Celik et al., 2004). However, it has been reported that the stabilizing effect of SOM is only a short-term one and that it diminishes with time (Sort and Alcaniz, 1999).

High levels of SOM seem to promote resistance to sodic conditions. A direct relationship has been noted between soil stability (inferred from modulus of rupture) and SOM content at any given ESP, especially for soils containing 10%-20% clay (Aylmore and Sills, 1982). Addition of pea straw to soils increased macroaggregate stability at ESP values of 3%-36% (Barzegar et al., 1996). The favorable effects of transient organic agents on aggregate stabilization can be explained by nonionic bonding mechanisms by which roots, hyphae, and natural polysaccharides stabilize aggregates, and which are not always directly affected by interactions between water, clay, and exchangeable cations. Nelson and Oades (1998) concluded that the beneficial effects of these transient agents on aggregate stability are most noticeable when ESP is not too high with adequate TEC to offset its effects, clay content is moderate, Mg content is low, mechanical disturbance is limited, and fresh organic materials are added regularly.

Additional sources of transient SOM are mucilages and sugars produced by plant roots and microorganisms. These materials are transient because they decompose readily (Nelson and Oades, 1998) and act as bonding agents in stabilizing smaller structural units (microaggregates) (Tisdall and Oades, 1982).

The persistent components of SOM include polyanionic colloidal materials (plant remains and microbial products), often referred to as humic substances. Their persistence results from their recalcitrance and association with inorganic materials

(Stevenson, 1992). These components play an important role in determining the stability of smaller scale aggregates (microaggregates) through a variety of mechanisms, but especially through their dispersing power. Organic anions are known to increase clay dispersivity, in particular when variable charge minerals are present, mainly by increasing the negative charge density of the soil colloid fraction. There is a large body of literature which documents the influence of organic anions on increasing the CFC of various clay minerals, thus giving rise to their susceptibility to dispersion (Frenkel et al., 1992; Tarchitzky et al., 1993; Nelson and Oades, 1998). High ESP, the presence of exchangeable Mg or high pH each increase clay dispersivity in the presence of organic anions (Emerson and Smith, 1970). Because humic substances form chelates with Ca (Sposito et al., 1977), the effective SAR of the soil solution increases, and clay dispersion is promoted.

There are, however, also indications that addition of humic fractions extracted from a variety of sources (permanent pasture soil, cattle manure, and raw oxidized coal, respectively) could be effective in improving aggregate stability (e.g., Piccolo et al., 1997). For instance, Imbufea et al. (2005) observed that addition of potassium-humate to a sodic (ESP = 17) Australian soil significantly improved its aggregate stability.

18.5 Water Flow in Sodic Soils

Sodicity-related degradation of soil structure leads to deterioration of soil water transmission properties, increased susceptibility to crusting, runoff, erosion, and poor aggregate stability. Water transmission properties of soils are commonly characterized by measuring HC and/or infiltration rate (IR), which are distinctly different; HC is measured under conditions where the soil surface in undisturbed, while IR is determined, generally, under conditions where considerable surface disturbance arising from external forces, such as raindrop impact, overhead irrigation, or the shear force of flowing water in furrows, occur. This disturbance often leads to surface seal formation, causing the rate of water movement in the sealed layer to be different from that in the underlying soil.

18.5.1 Hydraulic Conductivity

18.5.1.1 Introduction

The HC of a soil depends on its properties as well as those of the percolating liquid. A detailed discussion of HC is presented in Chapter 5 of *Handbook of Soil Sciences: Properties and Processes*. A number of models have been proposed to describe the relationships between structure of a porous material as reflected by its pore size distribution and permeability (Kozeny, 1927; Childs and Collis-George, 1950; Marshall, 1958). These types of models have not succeeded in adequately predicting soil HC, in part, because they do not take into account the effect of fluid properties on the soil matrix geometry. Clay swelling and dispersion in response to changes in electrolyte composition and

concentration of the percolating solution change the size of conducting pores, and hence HC.

18.5.1.2 Sodicity and Electrolyte Concentration

Fireman and Bodman (1939) and Bodman and Fireman (1950) advanced the concept that the higher the SAR and the lower the TEC of the percolating solution, the greater the reduction in soil HC. Subsequently, Quirk and Schofield (1955) developed the concept of threshold concentration, which they defined as the concentration required to prevent a decrease >25% in soil permeability for a given soil ESP or SAR of the percolating solution (Figure 18.6). According to Quirk and Schofield (1955), even a Ca-saturated soil (ESP = 0) may show a reduction in HC, provided that the TEC is below 0.6 mmol, L-1 which has been verified in other studies (Emerson and Chi, 1977). When rain or snow water (<1 mmol_c L⁻¹) is applied to a soil, even soils with very low ESPs may disperse causing permeability to decrease. The basic approach of Quirk and Schofield (1955) has been extended to a large number of additional soils (e.g., McNeal and Coleman, 1966; McNeal et al., 1966, 1968; Yaron and Thomas, 1968; Rhoades and Ingvalson, 1969; Cass and

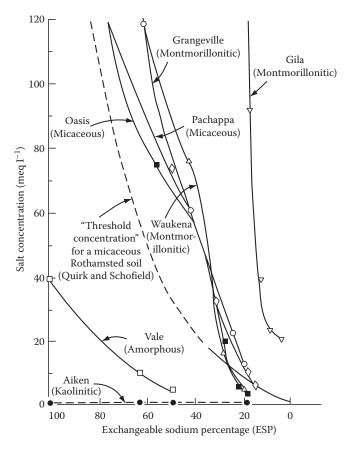

FIGURE 18.6 Combinations of salt concentration and ESP required to produce a 25% reduction in hydraulic conductivity for selected soils. (Reprinted from McNeal, B.L., and N.T. Coleman. 1966. Effect of solution composition on soil hydraulic conductivity. Soil Sci. Soc. Am. Proc. 30:308–312. With permission of the Soil Science Society of America.)

Sumner, 1982a, 1982b, 1982c; Levy et al., 2005; Dikinya et al., 2007; Bauder et al., 2008).

The importance of clay swelling and dispersion in controlling the HC has been highlighted by numerous studies (Quirk and Schofield, 1955; McNeal et al., 1966; Rowell et al., 1969; Cass and Sumner, 1974; Shainberg et al., 1981a; Radcliffe et al., 1987; Keren and Singer, 1988; Kosmas and Noutakas, 1990; Quirk, 2001). Soils begin to swell as the TEC of the soil solution is reduced, but the effect of swelling on HC becomes apparent only at SAR > 10 in medium and fine textured soils. In coarse textured soils, the effect of swelling on reducing the size of conducting pores, and hence on HC, is hardly noticeable. Because the swelling process is reversible, an increase in HC is observed when TEC is increased again. Clay dispersion, on the other hand, can take place even at low ESPs provided TEC < CFC. When clay dispersion occurs, the dispersed clay particles move through the soil profile and may even cause a complete blockage of conducting pores, and hence irreversible changes in the HC. Consequently, the effects of reducing TEC on the HC are likely to be more severe when clay dispersion is a predominant cause (Shainberg and Letey, 1984). However, the results of the study of Keren and Singer (1988) suggest that interactions between the swelling and the dispersion processes may exist and affect pore size and continuity and thus soil HC.

When Na-affected soils are exposed to rainfall or irrigation water of low TEC, their HC is reduced because the salt concentration in the soil solution is not sufficient to prevent swelling and clay dispersion. For instance, in Australia under rainfed conditions, soils (especially fine textured) often waterlog during the winter rainy season because what little salt is present is leached in the first rains, causing the clay to disperse and seal the soil (Fitzpatrick et al., 1994). In Israel, fields irrigated with water having SAR values as high as 26 with an EC of 4.6 dS m-1 showed no permeability problems because the TEC in the irrigation water was sufficient to prevent the dispersive effect of Na (Frenkel and Shainberg, 1975). However, upon applying DW to simulate winter rainfall, soil HC dropped to a small fraction of its initial value of 9-12 mm h⁻¹ (Frenkel and Shainberg, 1975). Similar permeability problems arising from a decrease in TEC of the percolating water have been reported for some areas in the Central Valley of California (Mohammed et al., 1979), and for numerous soils in South Africa (Hensley, 1969; Johnston, 1975). The interaction between SAR, low levels of TEC, and soil HC was studied by Shainberg et al. (1981a) who demonstrated that maintaining a TEC of 3 mmol_c L⁻¹ can be sufficient to prevent a decrease in HC for a solution having SAR < 12. However, recently Suarez et al. (2008) reported that the HC of undisturbed soil cores decreased when the SAR of the irrigation water was increased from 4 to 6 for solutions with TEC of 10 and 20 mmol_c L⁻¹.

A number of attempts have been made to relate clay swelling to changes in soil HC. Generally, two types of approaches have been considered, empirical and conceptual. The empirical approach, as represented by the work of Suarez and Simunek (1997), used the experimental results of McNeal et al. (1968), to portray the

effect of mixed Na/Ca salt solutions on the HC of California soils. The more conceptual, physically based approach was introduced by Russo and Bresler (1977) and is presented in detail by Russo (1988). In this approach, the physicochemical interactions between mixed Na/Ca solutions and the soil matrix are derived from theoretical considerations based on the mixed ion diffuse double-layer theory, the structure of clay particles, the pore size distribution of the soil, and hydrodynamic principles.

18.5.1.3 Soil Properties Affecting Sodic Behavior

18.5.1.3.1 Effect of Mineral Weathering

A major factor causing differences among various sodic soils in their susceptibility to hydraulic failure when leached with solutions having low TEC water is their rate of salt release during mineral dissolution (Rhoades et al., 1968; Felhendler et al., 1974; Shainberg et al., 1981a, 1981b; Shainberg and Gal, 1982; Alperovitch et al., 1985; Naidu et al., 1993b; Keren and Ben-Hur, 2003). Mineral dissolution often determines the TEC of percolating solutions and hence soil HC. Sodic soils containing minerals that readily release soluble electrolytes (CaCO3 and a few primary minerals) will not disperse immediately when leached with DW at moderate ESP values, because a sufficiently high TEC (3 mmol_c L⁻¹) is generally maintained to prevent clay dispersion. In addition, the ESP and SAR values will be reduced because most of the cations released are Ca and Mg. Conversely, soil solution concentrations in soils lacking readily weatherable minerals are likely to be below the CFC, making such soils more susceptible to clay dispersion and a reduction in HC when exposed to DW (Felhendler et al., 1974).

In soils containing CaCO₃, the fine CaCO₃ particles can, in addition to the above-mentioned dissolution effect, improve the physical condition and permeability of sodic soils by acting as a cementing agent in stabilizing soil aggregates (USSL Staff, 1954; Rimmer and Greenland, 1976; Keren and Ben-Hur, 2003), The relative importance of each of these mechanisms (i.e., dissolution and cementing) can be estimated from their effect on IR and crust formation under rainfed conditions (Agassi et al., 1981; Ben-Hur et al., 1985) (Section 18.5.2.2).

18.5.1.3.2 Effect of Clay Mineralogy

The type of clay mineral also influences the response of soils to sodic conditions. Soils with high contents of expanding 2:1 layer silicates (e.g., montmorillonite) are the most labile while those high in kaolinite and sesquioxides are the least labile (McNeal and Coleman, 1966; Yaron and Thomas, 1968). Acidic kaolinitic soils have been considered insensitive to changes in soil ESP; however, upon addition of smectitic impurities to these soils, their susceptibility to sodic conditions increased markedly (Frenkel et al., 1978). The HC of nonacidic arid and kaolinitic soils has been reported to decrease significantly upon exposure to sodic conditions (Frenkel et al., 1978; Abu-Sharar et al., 1987b). Among the 2:1 layer silicates, montmorillonitic soils have been found to have greater sensitivity to ESP than their vermiculitic counterparts (Rhoades and Ingvalson, 1969).

18.5.1.3.3 Effect of Soil Texture

Mobile clay in the leachate is usually only observed in sandy soils. When clay content is high, the small size of the conducting pores usually ensures that dispersed clay moves only short distances before it clogs the pores, thus leading to low HC. Therefore, in loams and clays, the dispersion mechanism still operates, but no macroscopic movement of the clay particles is observed. Conversely, in sandy soils, the dispersion mechanism and macroscopic clay movement become evident particularly at higher ESP levels, as was shown by Pupisky and Shainberg (1979). The decline and subsequent recovery in HC for a soil of ESP 20 (Figure 18.7) can be explained by a change in flow pattern from that of a solution flowing through a matrix of sand covered with clay which starts to disperse and reduce the HC, to flow of a clay suspension through a pure sandy matrix having large pores resulting in an increase in HC once more (Pupisky and Shainberg, 1979).

Recently, Shainberg et al. (2001) observed a significant interaction between soil clay content (a measure for soil texture) and sodicity with regard to their impact on the HC of semiarid soils. Similarly, Levy et al. (2005) noted that the response of soils' HC to sodic conditions depends on soil texture. However, the combined impact of clay content and soil ESP on the HC is difficult to predict. Clay content acts as a cementing agent binding primary particles into stable aggregates, hence higher clay content supports more stable aggregates (Kemper and Koch, 1966; Kay and Angers, 1999) that are less likely to break down and decrease the HC. Conversely, the greater the clay content the more effective clay swelling is in narrowing the water conducting pores. Changes in soil ESP affect soil swelling and dispersion. The reliance of the HC on both factors depends on the relative weight of each of these factors in determining the mechanism that affects the HC.

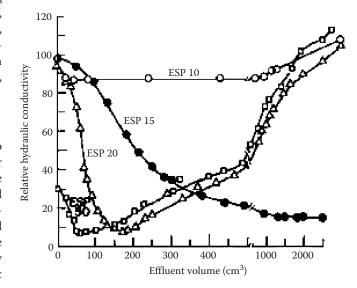

FIGURE 18.7 Relative hydraulic conductivity of soils with various ESPs leached with DW. (Reprinted from Pupisky, H., and I. Shainberg. 1979. Salt effects on the hydraulic conductivity of a sandy soil. Soil Sci. Soc. Am. J. 43:429–433. With permission of the Soil Science Society of America.)

18.5.1.3.4 Effect of Exchangeable Magnesium

Although the exchangeable Ca/Mg molar ratio is high in many soils, the reverse is true for some soils. The effect of adsorbed Mg on soil hydraulic properties is a controversial issue. The USSL Staff (1954) grouped Ca and Mg together with respect to their similarities in promoting and maintaining soil structure, while others have found that a Na-Mg-saturated soil is structurally less stable (van der Merwe and Burger, 1969) and/or has a lower HC (McNeal et al., 1968) than a Na-Ca-saturated soil. Alperovitch et al. (1981, 1985) related the effects of Mg to soil type. In calcareous soils, the presence of Mg enhances the dissolution of CaCO₃, thereby producing electrolytes which prevent clay dispersion and HC decay. In noncalcareous soils, Mg causes a decrease in HC of the soils beyond that of a corresponding Na-Ca system (Alperovitch et al., 1981, 1985). Shainberg et al. (1988) concluded that the lower HC values of Na-Mg relative to Na-Ca montmorillonite are related to the effect of Mg on the hydrolysis of montmorillonitic clay. The presence of a high concentrations of Mg at the clay surface slows down the release of octahedral Mg from the mineral lattice (Kreit et al., 1982), thereby lowering the EC of the Na-Mg clay (Shainberg et al., 1988). In kaolinitic soils, this adverse effect of Mg has not been noted (Levy et al., 1989).

A distinction has been made between the direct effect of exchangeable Mg in causing decreases in HC, which has been termed a specific effect, and the inability of Mg in irrigation water to counter the accumulation of exchangeable Na in soils (McNeal et al., 1968; Chi et al., 1977; Emerson and Chi, 1977; Rahman and Rowell, 1979). Curtin et al. (1994) concluded that the specific effect of Mg was dominant, because the observed adverse effects of Mg on clay dispersion and HC were greater than could be explained simply by a slightly higher exchangeable Na level in Mg systems.

18.5.2 Infiltration Rate

18.5.2.1 Introduction

Soil IR is defined as the volume flux of water flowing into the profile per unit surface area under any given set of circumstances. Mechanisms controlling changes in the IR over time depend on the mode of water application to the soil. Under conditions where water is supplied to the soil without appreciable energy input, IR depends on the HC of the soil matrix (Section 18.5.1). The IR is, generally, high during the early stages of infiltration, particularly when the soil is initially quite dry, but decreases monotonically to approach a constant rate asymptotically, due to a decrease in the matric suction gradient that occurs as infiltration proceeds (Baver et al., 1972; Hillel, 1980).

When water is supplied with appreciable energy impact, the IR decreases from its initial high rate due to the formation of a thin layer (<2 mm) at the soil surface, termed surface seal. This seal is characterized by greater density, higher shear strength, finer pores, and lower saturated HC than the underlying soil (McIntyre, 1958; Bradford et al., 1987). A structural seal, usually caused by the impact energy of waterdrops, should be

distinguished from a depositional seal formed by translocation and deposition of fine soil particles at a discernible distance from their original location (Chen et al., 1980; Arshad and Mermut, 1988). The discussion to follow will focus on the former type seal.

Structural seal formation is the result of two mechanisms: (1) physical disintegration of surface soil aggregates caused by wetting of the dry aggregates (Loch 1994; Levy et al., 1977) and/or the impact energy of raindrops (McIntyre, 1958; Morin and Benyamini, 1977; Agassi et al., 1981) or sprinkler irrigation (Aarstad and Miller, 1973), and subsequent compaction of the disintegrated aggregates by water drop impact, and (2) physicochemical dispersion of soil clays, which then migrate into the soil with the infiltrating water, clog pores immediately beneath the surface, and form a layer of low permeability (Farres, 1978; Agassi et al., 1981). The two mechanisms are complementary. The physical disintegration of surface soil aggregates enhances clay susceptibility to dispersion under sodic conditions (Shainberg and Letey, 1984), while clay dispersion weakens aggregate stability and renders them greater sensitivity to disintegration by wetting and/or the impact of water drops (Abu-Sharar et al., 1987a; Mamedov et al., 2001).

18.5.2.2 Effect of Sodicity on Infiltration Rate

Kazman et al. (1983) studied under laboratory conditions the sensitivity of seal formation and IR of smectitic soils to low levels of ESP when exposed to DW (simulating rainwater) (Figure 18.8). Even at the lowest sodicity (ESP = 1.0), a seal was formed and the IR dropped from an initial value >100 mm h⁻¹ to a final infiltration rate (FIR) of 7.0 mm h⁻¹. An ESP value of 2.2 was sufficient to cause a further drop in FIR of the sandy loam to 2.4 mm h⁻¹. The amount of rain required to approach the FIR was also affected by ESP (Figure 18.8). Because raindrop impact

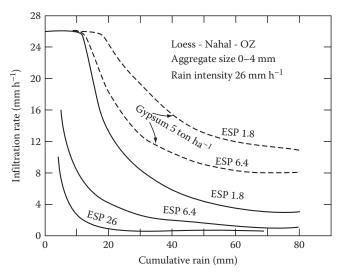

FIGURE 18.8 The effects of the soil ESP and phosphogypsum application on the infiltration rate of the Hamra–Netanya soil as a function of the cumulative rain. (Reprinted from Kazman, Z., I. Shainberg, and M. Gal. 1983. Effect of low levels of exchangeable Na and applied phosphogypsum on the infiltration rate of various soils. Soil Sci. 35:184–192. With permission from Wolters Kluwer Health.)

energy was the same in all experiments, the differences between IR curves for the various treatments reflect the result of chemical dispersion of soil clay caused by sodicity. The high sensitivity of the soil surface to low ESP values is explained by three factors (Oster and Schroer, 1979; Kazman et al., 1983): (1) the mechanical impact of the raindrops, which enhances chemical dispersion; (2) the absence of a surrounding soil matrix (sand particles), which when present slows clay dispersion and movement; and (3) the almost total absence of electrolytes in the applied DW. With respect to the first factor, it is difficult to separate the mechanical and chemical mechanisms that are complementary. Agassi et al. (1985a) noted that in the absence of the former, the chemical mechanism does not come into effect at low ESP levels (<5). Evidently, in the lower range of ESP, the chemical mechanism needs some activation energy before it can begin operating at the soil surface. In the case of rainfall, this energy is provided by the impact of the raindrops.

Clay dispersion is highly sensitive to the TEC and SAR of the applied water. This is particularly true in cases where the soil surface is exposed to the mechanical action of falling water droplets, which enhance clay susceptibility to chemical dispersion. Agassi et al. (1981) noted for two Israeli smectitic soils that, the lower the TEC, the faster the rate at which the IR decreases. Also for the same TEC, increasing soil ESP results in a sharper decrease in IR and a lower FIR. Similarly, Oster and Schroer (1979) found that TEC greatly affected IR even at low SAR values. They observed an increase in final IR from 2 to 28 mm h⁻¹ as TEC in the applied water (SAR 2 to 4.6) increased from 5 to 28 mmol_c L⁻¹. These results suggest that IR is far more sensitive than HC to the TEC of the applied water (Shainberg and Letey, 1984). Furthermore, the IR values of calcareous and noncalcareous soils are equally sensitive to low levels of ESP (Agassi et al., 1981; Kazman et al., 1983), whereas the HC of calcareous soils is less sensitive to sodic conditions than that of noncalcareous soils (Section 18.5.1.3). These findings indicate that (1) the rate at which lime dissolves and increases TEC in the soil is insufficient when the soil is exposed to rainfall, and (2) the role of CaCO₃ as a cementing material is negligible, because otherwise both types of soil would have had different IR values (Shainberg and Letey, 1984).

Although Ca and Mg are both divalent cations, their effects as the complementary cation to Na on soil stability are often very different. Elevated exchangeable Mg levels can cause deterioration in soil structure resulting in the development of a Mg solonetz (Ellis and Caldwell, 1935). In addition, Mg enhances dispersion of montmorillonitic and illitic clays compared to Ca (Bakker and Emerson, 1973). With respect to IR, the effect of exchangeable Mg has been found to depend on the kinetic energy of the water droplets. When high energy rain (22.9 kJ m⁻³) was used, exchangeable Mg had an effect similar to that of Ca (Levy et al., 1988), but with low to medium energy rainfall (8.0-12.5 kJ m⁻³), the IR of Mg-Na-treated soil was lower than that of Ca-Na soil (Keren, 1990). Such findings suggest that the adverse effect of Mg on clay dispersion, and hence on IR, is pronounced only under conditions where chemical dispersion controls IR (i.e., for raindrops with low to medium kinetic energy).

The susceptibility of sodic soils to seal formation and reduction in IR when exposed to rainfall depends on a number of soil properties, and especially on clay content and mineralogy. Soils with 10%–30% clay are considered as the most susceptible to seal formation and have the lowest IR values. With increasing clay content, soil structure is more stable and seal formation diminishes. In soils with lower clay contents (<10%), the amount of clay available to disperse and clog soil pores is limited and, as a result, only a poorly developed seal can be formed (Ben-Hur et al., 1985).

Most of the studies on seal formation and IR have been conducted on soils in which the dominant clay minerals are smectites that are known to be dispersive during both HC and IR determinations. The effect of exchangeable Na on the HC of kaolinitic soils is quite small (Frenkel et al., 1978; Chiang et al., 1987); however, a number of kaolinitic and illitic soils from the southeastern United States (Miller, 1987; Miller and Scifres, 1988) and Africa (Levy and van der Watt, 1988; Stern et al., 1991; Wakindiki and Ben-Hur, 2002) have been found to be susceptible to seal formation. Evidently, upon mechanical agitation by the beating action of raindrops, aggregates from kaolinitic soils may disperse (according to the level of exchangeable Na), and consequently, form a seal with a resultant low IR. Additionally, Stern et al. (1991) observed that the susceptibility of kaolinitic soils to seal formation was positively correlated with their contents of smectitic impurities; kaolinitic soils with small amounts of smectite were dispersive and susceptible to seal formation, whereas kaolinitic soils that contained no smectite impurities were less susceptible.

Seal formation and reduction in IR depend strongly on clay dispersion, which is enhanced by increasing soil ESP and/or decreasing TEC. In addition, a strong relation between dispersible clay, IR, and soil loss has been reported in numerous studies (Miller and Baharuddin, 1986; So and Cook, 1993). Sumner (1993) compiled a table based on published data showing that, for soils from different regions of the world, IR decreases as SAR/ESP increases, making more water available for runoff which, in turn, tends to increase erosion (Table 18.2). A different view of the relation among soil ESP, IR, and erosion was given by Levy et al. (1994), who did not observe a direct relationship between these factors. They argued that with an increase in ESP a lower IR is obtained, but the resultant erosion depends on the balance between the larger volume of runoff and a more dense and structurally more resistant seal; thus the amount of erosion cannot be predicted.

18.5.2.3 Sodicity and Conditions Prevailing in the Soil

The interest in the effects of conditions prevailing in the soil on its susceptibility to seal formation stems from the realization that aggregate stability, which seal formation is closely related to, depends, in addition to its association with various soil properties (e.g., organic matter, clay percentage, and oxides content), on conditions prevailing in the soil such as rate of aggregate wetting, antecedent moisture content (AMC) in the aggregates, and aging duration (Panabokke and Quirk, 1957; Francis and

Cruse, 1983; Kjaergaard et al., 2004). Aggregate disintegration by wetting, termed *slaking*, increases with the increase in their rate of wetting and is ascribed to the explosion of aggregates by entrapped air and differential swelling (Panabokke and Quirk, 1957; Quirk and Panabokke, 1962). Wetting and keeping the soil at a given moisture (i.e., aging) induces an increase in aggregate strength through the development of cohesive bonds between the soil particles (Blake and Gilman, 1970; Kemper and Rosenau, 1984; Attou et al., 1998) and the production of cementing agents by microbial activity (Martin et al., 1995). The effects of aging duration on aggregate stability seem however to depend on the AMC of the soil (Gerard, 1965; Utomo and Dexter, 1981). The effects of these conditions on soil sealing as well as their interactions with one another and with several soil and rain properties has been summarized recently in a review by Ben-Hur and Lado (2008).

Early studies on the effect of wetting rate (WR) on soil vulnerability to sealing clearly indicate that when slow wetting is used (i.e., eliminating aggregate slaking), surface aggregates are considerably less susceptible to disintegration by the impact of raindrops, and thus less developed and more permeable seals are formed (Loch, 1994; Levy et al., 1997). However, results of various studies show that use of slow WR to prevent slaking and maintain high IR occurs mainly in fine textured soils (Mamedov et al., 2001; Shainberg et al., 2003, Lado et al., 2004). Mamedov et al. (2001) studied the combined effects of WR (2, 8, and 64 mm h⁻¹), soil sodicity (ESP levels between 0.9 and 20.4), and

texture (clay content from 8.8% to 68.3%) on IR and runoff from six Israeli soils; data for runoff are presented in Figure 18.9. In soils with low clay content (8.8%), effect of WR on seal formation was negligible, whereas effect of ESP was significant. Conversely, in the clay soils (>52.1%), WR had a predominant effect on IR and runoff, while the effect of ESP was notable yet secondary to that of WR. The soils with intermediate clay content (22.5%–40.2% clay) were the soils most susceptible to seal formation, with both WR and ESP having moderate effects on seal formation and runoff (Figure 18.9).

The dependence of aggregate stability on AMC has been linked to aggregate detachment, soil erosion, and seal formation (Farres, 1987; Bradford et al., 1992; Le Bissonnais, 1996; Levy and Mamedov, 2002). Furthermore, moisture content together with aging duration have been found to determine aggregate breakdown mechanism, the resulting particle size distribution, and the evolution of the structure of the seal (Kemper and Rosenau, 1984; Le Bissonnais, 1990). The direct impact of AMC on seal formation and soil loss has received extensive attention (Cruse and Larson, 1977; Al-Durrah and Bradford, 1981; Francis and Cruse, 1983; Luk, 1985; Reichert and Norton, 1994; Le Bissonnais et al., 1995; Froese et al., 1999; Wangemann et al., 2000) but results were inconsistent albeit using nonsodic soils. Conversely, the effect of aging on sealing was studied less. Levy et al. (1997) reported of the existence of an interaction between aging and WR in their effect on the IR. Ageing duration of 18h was only effective in maintaining higher IR in cases where the

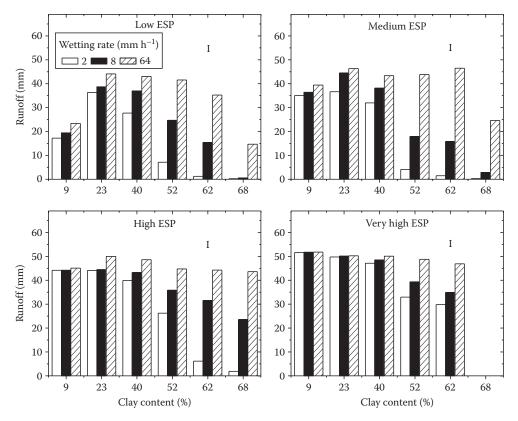

FIGURE 18.9 Effects of wetting rate on the calculated runoff from six soils as a function of clay content and ESP. Bar indicates a single confidence interval value. ESP low, medium, high, and very high refers to 2, 5, 10, and 20, respectively. (Reprinted from Mamedov, A.I., G.J. Levy, I. Shainberg, and J. Letey. 2001. Wetting rate and soil texture effect on infiltration rate and runoff. Aust. J. Soil Res. 30:1293–1305. With permission of CSIRO Publications, Melbourne, Australia.)

WR was not fast ($<6\,\mathrm{mm\ h^{-1}}$). When fast WR was used, similar IR curves were obtained for aged- and non-aged samples (Levy et al., 1997). Ben-Hur et al. (1998) observed for a nonsodic and a sodic soil that 4 days of aging resulted in a more gradual decrease in the IR curve and a higher final IR compared to a nonaged soil.

Recently, Mamedov et al. (2006) studied the combined impact of AMC and aging. These authors reported of the existence of an optimal range of AMC, generally between field capacity and wilting point, at which runoff levels were 30% lower than those obtained below or above this AMC range. They also observed that the level of AMC determined the beneficial effects of aging on improving the resistance of soil to seal formation. Increasing aging duration was most effective in improving soil IR at the aforementioned optimal level of AMC studied. It can be expected, based on current knowledge, that the effects of AMC and aging would be greatly affected by the degree of soil sodicity.

18.6 Crop Responses to Sodic Conditions

Productivity of sodic soils is limited, mainly because the deterioration in their physical properties (Cairns et al., 1962; Minhas, 1996; Oster and Jayawardane, 1998), which causes poor aeration, restricts root development, and enhances root diseases. These not only decrease crop yields but also limit the choice of

crops that can be grown on these soils (Ayers and Westcot, 1985; Minhas, 1996; Oster and Jayawardane, 1998). In addition, sodic conditions can also change soil redox potential, pH, dissolved organic C content, and bicarbonate toxicity (Chauhan et al., 2007), all of which could lead to nutritional imbalances (Qadir and Oster, 2004). For a detailed review of crop response to sodicity and sodicity-related fertility and nutritional constraints, readers are referred to Curtin and Naidu (1998).

18.6.1 Crop Tolerance to Sodicity

Research on crop tolerance to sodicity has been conducted under two different types of conditions, in the presence or in the absence of sodicity-related adverse soil physical conditions. In the United States, research has focused mainly on tolerance to sodicity based solely on nutritional factors (Chang and Dregne, 1955; Pearson and Bernstein, 1958), because in the field, sodicity-induced nutritional imbalances may be obscured by unfavorable physical conditions (Bernstein and Pearson, 1956). Data presented by Pearson (1960) indicate that even at relatively low ESP levels (2–10), some crops show signs of Na toxicity. However, most field crops can be classified as moderately tolerant or tolerant to sodicity (Pearson, 1960). Work in India, on the other hand, has been carried out under conditions where soil structure was allowed to be affected by sodicity concurrently

(Abrol and Bhumbla, 1979; Singh et al., 1979). Under such conditions, grasses were tolerant, wheat and barley were moderately tolerant, and pea and beans were sensitive to sodicity (Gupta and Abrol, 1990). Recently, Garg et al. (2005) observed that fennel crop was tolerant to sodicity up to ESP of 25. Use of the concept where the soil is allowed to be affected by sodicity may, however, cause results to be site specific, and hinder their applicability to other locations and soil types. Furthermore, ranking of crops for sodicity tolerance depends on the conditions under which the response was determined. For instance, rice has been found to be highly tolerant under sodic field conditions (Abrol and Bhumbla, 1979), but only moderately tolerant under favorable soil conditions (Pearson, 1960).

18.6.2 Plant Nutrition in Sodic Soils

Field fertility studies on sodic soils often yield inconclusive results, mainly due to high spatial variability (Toogood, 1978). Consequently, most dependable data on sodicity-related nutritional aspects have been obtained from greenhouse and laboratory studies (Curtin and Naidu, 1998; Wright and Rajper, 2000).

Of the three major cations found in the soil in addition to Na (Ca, Mg, K), availability of Mg (Williams and Raupach, 1983) and K (Chhabra, 1985) have not been considered to be of a major concern in sodic soils. Jalali et al. (2008) point, however, to the fact that during irrigation with sodic water, leaching of Mg and K from the root zone can occur, and if uncorrected especially in soils with low CEC, could lead to their deficiencies to plant growth. Unlike Mg and K, impaired uptake of Ca is one of the main adverse nutritional effects of sodic soils, probably due to low Ca concentrations in the soil solution (Wright and Rajper, 2000). Calcium plays a major nutritional and physiological role in plant metabolism. The ratio of Ca to total cation concentration (TCC) is considered to be a better indicator of Ca availability to plants than the actual Ca concentration (Adams, 1974). Carter and Webster (1990) found that Ca/TCC values <0.1 are often found in saturated paste extracts of sodic soils, which for many crops, would result in Ca deficiency (Grieve and Maas, 1988). In addition, high Mg/Ca ratios, which are often found in sodic soils (Williams and Colwell, 1977), can also cause Ca deficiency (Grattan and Grieve, 1992). Extreme ratios of Na:K, Mg:Ca, and Cl:NO₃ (Curtin and Naidu, 1998; Grattan and Grieve, 1999), likely to be found in the soil solution of sodic soils, rather than absolute values, may lead to salt-stressed plants, specific-ion toxicity, and nutritional disorders (Grattan and Grieve, 1999).

Except for the case of weathered sodic soils in Australia, where acute phosphorus (P) deficiency is a frequent occurrence (Naidu and Rengasamy, 1993), P does not pose a nutritional problem in sodic soils; some studies even reported that P is more readily available to plants in sodic than in nonsodic soils (Chhabra, 1985; Gupta et al., 1990). Nitrogen (N), on the other hand, can limit growth in many sodic soils (Cairns et al., 1967; Malhi et al., 1992) because of low rates of N mineralization, denitrification under restricted aeration conditions, volatilization of NH₃

under alkaline conditions, and inhibition of NO_3 uptake by Cl or SO_4 ions, which usually are in abundance (Curtin and Naidu, 1998; Grattan and Grieve, 1999).

Poor productivity of sodic soils can also be ascribed, at least in part, to micronutrient deficiencies in the soil (Naidu and Rengasamy, 1993). Availability of micronutrients in sodic soils is controlled largely by adsorption and precipitation reactions. Neutral pH values generally enhance adsorption of micronutrients. The composition and concentration of the soil solution also determine plant availability of micronutrients. The extent to which these solution parameters affect the availability has not yet been well established (Curtin and Naidu, 1998); the presence of carbonate minerals that provide active sorption sites for the precipitation of many micronutrients should further reduce their availability (Hodgson et al., 1966). Micronutrient deficiencies could also stem from difficulties in their uptake by the plants due to lower dry weight of the various types of tissues of the plant (Wright and Rajper, 2000).

18.6.3 Ion Toxicity under Sodic Conditions

Apart from the osmotic effect on plants due to high TEC generally found in sodic soils, high concentrations of Na have been found to be toxic in some woody species (Maas and Hoffman, 1977) and in avocado, citrus, and stonefruit trees (Lauchli and Epstein, 1990).

High Na/Ca ratios result in high Na uptake and low uptake of Ca by plants and thus cause, in addition to Ca deficiency, some other nutritional imbalances and adverse physiological effects (e.g., membrane permeability and plant stability). High Na uptake can cause deficiencies of elements such as K, Zn, Cu, and Mn, while low uptake of Ca enhances uptake and possible toxicity of elements such as Ni, Pb, Se, Al, and B (Levitt, 1980). Ameliorating sodic soils with gypsum or lime may (1) alleviate heavy metal toxicity, and (2) offset the negative effects created by excessive Na uptake on physiological processes in plants (Rengasamy, 1987). However, in layers where calcium carbonate has accumulated during pedogenesis, sodium bicarbonate and carbonate may accumulate, thereby increasing the soil pH above 9 (Rengasamy et al., 2003). In addition to the toxicity of carbonate and bicarbonate species, high pH also leads to Fe, Mn, Cu, Zn, and P deficiency (Naidu and Rengasamy, 1993). Furthermore, recent observations (Ma et al., 2003) have shown the phytotoxicity of Al(OH)₄ in soils with pH above 9.

Boron (B) is fairly soluble in sodic soils with neutral pH; thus B is likely to be toxic rather than deficient in these soils (Naidu and Rengasamy, 1993). Significant B toxicity in cereals was noted in regions of low rainfall of southern Australia; toxic concentrations of B in excess of 10 mg kg⁻¹ were recorded in subsurface layers of soils from these regions where sodic conditions prevail (Cartwright et al., 1986). Reclamation of sodic soils having pH > 7 with gypsum and leaching reduce B concentrations in the soil solution to levels within the safe limits, and B is no longer toxic to plants (Gupta and Abrol, 1990). For more details on B in soils readers are referred to Chapter 17 in this handbook.

18.7 Amelioration and Management of Sodic Soils

Management of sodic soils, involving the improvement in soil structure (to alleviate problems of water permeability and logging, erosion, inadequate aeration, compaction, etc.), is essential if productivity is to be maintained. Over the past 100 years, several different site-specific approaches involving the use of chemical amendments, tillage, crop diversification, water, and electrical currents have been used to ameliorate sodic soils (Qadir et al., 2001). Of these, chemical amendments have been used most extensively (Oster et al., 1999). A number of tillage options such as deep ploughing and subsoiling have also been used to break up the shallow, dense, sodic clay pans and/or natric horizons that occur within 0-4 m of the soil's surface (Abdelgawad et al., 2004). However, in recent decades, a crop-based approach (phytoremediation, biological reclamation, or vegetative bioremediation) has received considerable attention in many developing countries, as it is much cheaper than chemical amelioration, the costs of which are prohibitively high (Robbins, 1986; Qadir et al., 2001, 2002, 2006, 2007; Ghaly, 2002; Qadir and Oster, 2004).

18.7.1 Use of Chemical Amendments

There are two common practices for ameliorating sodic soils by addition of divalent cations: (1) using chemical amendments that release Ca ions to the soil and (2) application of successive dilutions of a high salt water containing divalent cations. Detailed reviews on the amelioration of sodic soils with those practices have been published by Keren (1995), Oster and Jayawardane (1998), and Qadir et al. (2001).

18.7.1.1 Chemical Amendments

Typical amendments are those containing a source of soluble or potentially soluble Ca when reacted with the soil. Common amendments include gypsum, lime, CaCl₂, H₂SO₄, and sulfur.

18.7.1.1.1 Gypsum

Gypsum ($CaSO_4 \cdot 2H_2O$), both from natural and anthropogenic sources (byproducts), is the most commonly used amendment for sodic soil reclamation, primarily because of its low cost, reasonable solubility, and availability. Gypsum added to a sodic soil can increase aggregate stability (Lebron et al., 2002; Mamedov et al., 2007) and soil permeability (Kazman et al., 1983) by means of both EC and cation exchange effects (Loveday, 1976).

The relative importance of each of these effects depends on the purpose for which gypsum is used. If gypsum is used in order to maintain high permeability at the soil surface during application of good quality water (i.e., rainwater or other source of water with low TEC), then the electrolyte effect is important. In this case, surface application of gypsum may be worthwhile, and the dissolution rate of gypsum dictates whether the rate of electrolyte supply to the water is sufficient to prevent clay dispersion and swelling. Thus, because of its higher dissolution rate, gypsum from industrial sources such as by-products of the

phosphate (phosphogypsum) and power generation (flue gas desulfurization gypsum) industries is preferable to mined gypsum (Keren and Shainberg, 1981). In this case, the amount of gypsum required depends on the amount of high quality water applied and the rate of gypsum dissolution, and is relatively independent of the amount of exchangeable Na in the soil profile. Field experiments in smectitic Israeli soils in a region of annual precipitation of 350-400 mm indicated that surface application of 5 Mg ha⁻¹ of phosphogypsum is effective in maintaining significantly higher IRs and lower runoff and soil loss levels compared with a nontreated soil (Keren et al., 1983; Agassi et al., 1985b). Furthermore, Kazman et al. (1983) reported that addition of phosphogypsum proved effective in maintaining high IR compared to the control, even in soils with ESP < 2 (Figure 18.8). This, once again, demonstrates that some chemical dispersion takes place even at very low ESP values. Use of phosphogypsum was found effective in preventing runoff also in kaolinitic soils (Miller, 1987; Miller and Scifres, 1988). Agassi et al. (1986) suggested that the favorable effect of phosphogypsum on preventing the decline in the IR should be attributed not only to its effect on the EC of the percolating water, but also to (1) physical interference with the continuity of the seal and (2) partial mulching of the surface protecting it from the beating action of raindrops.

Conversely, in soils where the high ESP of the soil profile needs to be reduced, then the cation exchange effect is more important. The amount of gypsum required depends then on the level of exchangeable Na in a selected depth of soil. The amount of exchangeable Na to be replaced per unit land area during reclamation depends on the initial and desired final exchangeable Na levels, CEC, bulk density, and depth of soil to be reclaimed. The amount of gypsum required (GR, Mg ha⁻¹) can thus be calculated by the following equation (Oster and Jayawardane, 1998):

$$GR = 0.0086 \cdot F \cdot D_s \cdot \rho_b \cdot CEC \cdot (ESP_i - ESP_f)$$
 (18.6)

where

F is the Ca–Na exchange efficiency factor (unitless)

 D_s is the soil depth to be reclaimed (m) ρ_b is the soil bulk density (Mg m⁻³)

CEC is the cation exchange capacity (cmol_c kg⁻¹)

ESP_i and ESP_f are the initial and final ESP values, respectively

Efficiency and percentage of Ca exchange for adsorbed Na increase with the increase in soil ESP (Chaudhry and Warkentin, 1968). Thus, the F factor ranges from 1.1 for an $\mathrm{ESP_f}$ of ~15 to 1.3 for an $\mathrm{ESP_f}$ of 5 (Oster and Frenkel, 1980). In addition, F increases with increasing clay content (Manin et al., 1982).

The cation exchange process, major ion species, complexation reactions, and mineral dissolution have formed the basis of several gypsum requirement models (Dutt and Terkeltoub, 1972; Tanji et al., 1972; Suarez, 2001), which have been field tested and yielded a satisfactory match between calculated and measured data. These models provide a powerful tool for quantitative predictions of water and gypsum required to reclaim a soil to a predetermined level of salinity and sodicity. Recently, Simunek and

Suarez (1997) have proposed a one-dimensional multicomponent transport model, UNSTACHEM, that takes into consideration, in addition to the parameters used by the aforementioned models, soil hydraulic properties and water flow velocities to predict the amendment concentration necessary for significant improvement of soil permeability.

18.7.1.1.2 Calcium Carbonate

Adding CaCO₃ to reclaim sodic soils is only of limited value (Gupta and Abrol, 1990), mainly because of its low dissolution rate that fails to provide an adequate amount of Ca for exchange. However, under certain conditions, naturally occurring carbonate minerals [CaCO₃, MgCO₃, CaMg(CO₃)₂] can play a significant role in reclaiming sodic soils (Inskeep and Bloom, 1986; Nadler et al., 1996). Dissolution of CaCO₃ can be enhanced by adding an acid or acid former to the soil (Keren, 1995) or by increasing CO₂ levels in the soil (Simunek and Suarez, 1997). The latter can be achieved by enhancing root activity (Bower and Goertzen, 1958; Rao and Ghai, 1985).

Normally, the beneficial effect of naturally occurring CaCO₃ on soil reclamation manifests itself mainly by maintaining the TEC of the soil solution at a level high enough to prevent clay dispersion and subsequent HC reductions (Felhendler et al., 1974; Alperovitch et al., 1981). However, CaCO₃ is not effective in maintaining high HC at the soil surface during rainfall because it fails to supply electrolytes fast enough at the soil surface, and thus, IR is impeded (Shainberg and Letey, 1984).

18.7.1.1.3 Acids and Sulfur

In calcareous soils, addition of acid amendments will react with $CaCO_3$ to produce a soluble source of Ca ($CaSO_4 \cdot 2H_2O$ or $CaCl_2$). In the case of elemental S additions, the process is somewhat more complicated as it requires an initial phase of microbiological oxidation to produce H_2SO_4 (Keren, 1995). The increasing availability of acid waste products, coupled with the need to dispose of them in a safe manner, increases their potential for use as soil amendments (Miyamoto et al., 1975; Sadiq et al., 2007).

18.7.1.1.4 Calcium Chloride

Calcium chloride (by-product from industry) can at times be an economical amendment for soil reclamation. Under certain conditions, such as soils with high ESP, CaCl₂ can be an even more efficient amendment than gypsum because of its higher solubility (Alperovitch and Shainberg, 1973), but it has only a short-term effect. Prather et al. (1978) suggested that for soils with high ESP and low permeability, a combined application of CaCl₂ and gypsum might give a more rapid and more effective reclamation than that of either amendment alone.

18.7.2 High Salt Water Dilution Method

In areas where water is not a limiting factor, reclamation of sodic soils can be achieved by leaching the soil with successive dilutions of high salt water containing divalent cations (Reeve and Bower, 1960). In the early stages, the high TEC prevents clay dispersion

and induces flocculation of the soil colloids. Simultaneously, the Ca ions in the water decrease sodicity by replacing exchangeable Na. Upon dilution of the saline water with higher quality water, the SAR of the water is reduced. Reeve and Doering (1966) developed a nomograph that predicts reclamation at any stage of leaching. However, to ensure successful soil reclamation, the depth of water added should be ninefold the depth of soil to be reclaimed (Reeve and Doering, 1966).

Among the various methods of water application during reclamation, sprinkler irrigation was found to be the best in removing salts from small pores (Nielsen et al., 1966) followed by intermittent ponding, which requires less water than continuous ponding to obtain a similar degree of leaching (Miller et al., 1965), thereby allowing time for salts to diffuse from soil aggregates to previously well-leached pores prior to the next leaching event.

Qadir et al. (2001) summarized the pros and cons of the high salt water dilution method as follows. The method is effective (1) in smectitic soils with low hydraulic conductivity, (2) when the physical conditions of the soil have been deteriorated to such an extent that use of ameliorants requires excessive amounts, and (3) in the case where the irrigation water to be used after amelioration is of very low electrolyte concentration. Problems associated with this method include (1) use of water containing inadequate concentration of divalent cations, (2) the need to develop facilities that collect, convey, and treat the saline water, and (3) the need to dispose of the highly saline-sodic drainage water in such way that soil, and surface and groundwater contamination is avoided (Qadir et al., 2001).

18.7.3 Tillage

Tilling sodic soils, which often results in improvements in physical and hydraulic properties, reduces bulk density, and increases total porosity (Blackwell et al., 1991), especially macroporosity (Klute, 1982), improves internal drainage and saturated and unsaturated HC. Consequently, aeration is improved and plant growth is enhanced (Oster and Jayawardane, 1998; Sadiq et al., 2007). However, the beneficial effects of tillage on sodic soils are often not long lasting because sodic soils tend to reconsolidate under their own weight when wetted, and their hydraulic properties deteriorate once more (Mead and Chan, 1988).

Deep tillage (1–2 m) or ripping breaks up hardpans and cemented layers, mixes soil layers and causes, in general, a permanent improvement in soil structure and physical properties. In order to obtain optimal results, plowing should be carried out at the correct soil moisture content, 10% for clay, 5% for loam, and 2.5% (w/w) for sand (Wildman, 1981). Sadiq et al. (2007) observed that disc plow was more effective in obtaining high yields and lower soil salinity parameters, in three sites in Pakistan compared to rotavator and cultivator. However, deep tillage can sometime lead to water logging and infiltration problems by bringing sodic subsoil to the surface (McKenzie et al., 1992). Shallow tillage (disking or chiseling) is effective in reducing soil permeability problems associated with surface crusts, hardsetting, and compaction. Shallow tillage requires repetition from time to time (Rawitz et al., 1986).

A combined treatment of tillage and gypsum application, termed gypsum slotting, has recently been developed in Australia, in which gypsum at rates sufficient to reclaim the treated soil is added in tilled slots created by tillage (~150 mm wide, 0.4 m deep and spaced about 1-2 m apart) (Jayawardane and Blackwell, 1986). The advantages of this technique include efficient removal of excess water from the surface layer and its storage in the subsoil for use during dry periods, reclamation of the soil in the slots, and maintenance of adequate macroporosity. In addition, compaction of the soil in the slots is prevented by the use of bridging implements (Blackwell et al., 1989). Results from field studies indicate that gypsum slotting improves aeration and infiltration and results in higher yields (Jayawardane et al., 1987). Gypsum slotting will not be effective where a shallow water table exists, or where subsoil permeability is higher than that of the topsoil, or for crops that require prolonged ponding (Jayawardane and Chan, 1994).

An additional method of combining tillage with gypsum application consists of spreading gypsum on the soil surface at a rate calculated to reclaim the sodic soil to a predetermined depth (Equation 18.6) and tilling to mix the gypsum into the soil, followed by an additional surface application of gypsum to maintain high IR and reduce exchangeable Na at the soil surface (Oster and Jayawardane, 1998).

18.7.4 Vegetative Remediation

Amelioration of sodic soils using vegetation has been extensively reviewed by Qadir et al. (2007). Vegetative remediation treatments are effective largely through their effects on both the physical and the chemical properties of sodic soils. Crop roots can stimulate changes in physical properties of the root zone in several different ways such as removal of entrapped air from larger conducting pores, generation of alternate wetting and drying cycles, and creation of macropores (Qadir and Oster, 2004). Aggregate stability is enhanced because of in situ production of polysaccharides and fungal hyphae in conjunction with differential dewatering at the root-soil interface (Tisdall, 1991). Instead of deep plowing, which at times could aggravate rather than improve soil conditions (Section 18.7.3), vigorous rooted rotation crops can also alleviate subsoil compaction. An alternative to subsoil amelioration is the use of ridge instead of bed farming techniques. With ridges, the plants are located ~0.25 m above the neighboring furrows, and, thus, aeration is improved, especially in fine textured soils suffering from water logging in the subsoil (Hunter et al., 1980; Hearn and Constable, 1984).

Cropping in sodic soils affects the chemistry of the root zone environment, especially in calcareous soils, via a series of processes: (1) enhancing the pCO_2 , (2) dissolution of CO_2 in water to form carbonic acid (H_2CO_3) and its immediate dissociation to proton (H^+) and bicarbonate (HCO_3^-), (3) reaction of H^+ with soil $CaCO_3$ to produce Ca, (4) Na-Ca exchange at the soil's cation exchange sites, (5) leaching of the exchanged Na^+ in the percolating water, and (6) subsequent reduction in soil sodicity (Qadir and Oster, 2004).

Removal of aboveground biomass of plant species, used for phytoremediation of sodic and saline-sodic soils, removes salts and Na taken up by the plants and accumulated in their shoots (Qadir et al., 2007). Highly salt-resistant species such as halophytes may accumulate quite high levels of salts and Na in their shoots. Qadir et al. (2003) found, however, that Na removal by shoot harvest of crops such as alfalfa would contribute to only 1%–2% of the total Na removed during phytoremediation of a sodic soil. It was concluded, therefore, that the principal source of sodicity decrease through phytoremediation of calcareous sodic soils is leaching of salts and Na from the root zone to deeper soil depths rather than removal by harvesting the aboveground plant biomass (Qadir et al., 2007).

The efficiency of various plant species for amelioration of sodic soils has been found to vary, possibly due to differences in their tolerance to salinity (Maas and Grattan, 1999), which often accompanies sodicity. In general, the species with greater production of biomass together with the ability to withstand ambient soil salinity and sodicity, and periodic inundation have been found efficient in soil reclamation (Ghaly, 2002; Qadir et al., 2002; Qadir and Oster, 2004). A summary of 17 lysimeter and field experiments showed that vegetative remediation was somewhat less effective than chemical amelioration in reducing soil sodicity (Figure 18.10). The chemical treatment

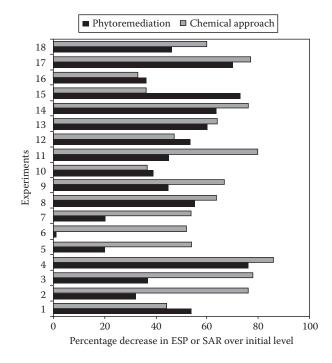

FIGURE 18.10 Summary of 17 experiments where chemical and phytoremediation treatments have been compared for their effects on a decrease in soil sodicity (SAR or ESP). The bars for respective treatments indicate percentage decrease over the respective levels of original soil SAR or ESP values. Number 18 is the mean values of the 17 experiments. (Reprinted from Qadir, M., J.D. Oster, S. Schubert, A.D. Noble, and K.L. Sahrawatk. 2007. Phytoremediation of sodic and saline-sodic soils. Adv. Agron. 96:197–247. Copyright 2007, with permission from Elsevier.)

(application of gypsum in all experiments) caused on average a 60% decrease in original sodicity level (ESP or SAR), whereas a 48% decrease was calculated for the vegetative remediation (Qadir et al., 2007).

Hodgson and Chan (1984) showed that using sunflower in rotation with cotton improved macroporosity and cotton root growth in a clay soil. Jayawardane et al. (1994) showed that growing sunflower in a gypsum slotted soil led to efficient and rapid extraction of water causing the soil to crack; in subsequent irrigation/rainfall events, infiltration thus increased. In other studies, the use of Kaller grass (Akhter et al., 2004), alfalfa (Ilyas et al., 1993), or sordan (Robbins, 1986) was recommended for soil amelioration. Rice is also commonly used, especially in the initial stages of reclamation, because of its tolerance to sodicity as well as the waterlogged conditions that favor reclamation (Abrol and Bhumbla, 1979). Chhabra and Abrol (1977) suggested that in gypsum-treated sodic soils rice should be the first crop. It should, however, be borne in mind that crops used in sodic soils may experience oxygen deficiency especially when excessive irrigations are used to leach the soil. Thus, evaluation of crops for the amelioration of sodic soils should consider also their resistance against hypoxia (Qadir et al., 2001; Qadir and Oster, 2004).

When cropping is not possible, pastures, green manure crops, and agroforestry can also contribute to soil amelioration (Dahiya and Anlauf, 1990; Singh et al., 1994). In their detailed review of the pros and cons of amelioration while cropping with various pasture grasses and trees, Nelson and Oades (1998) suggest that, for maximum benefit, organic matter and crops must be used in conjunction with chemical amendments and irrigation.

Addition of organic ameliorants (farm manure, plant residues), which similar to cropping leads to an increase in the pCO $_2$ in the soil, is also a widely recognized practice for reclaiming sodic soils. Application of organic matter is most effective in ameliorating alkali (soils with high pH) sodic soils. However, its ameliorative effects are generally restricted to the surface horizons where organic matter inputs tend to concentrate (Nelson and Oades, 1998). Because successful reclamation with organic materials must involve leaching, irrigation must be frequent and in small amounts (Dahiya and Anlauf, 1990). Reclamation under rainfall can be expedited by minimizing runoff and evaporation, and increasing infiltration.

18.8 Environmental Aspects of Sodic Soils

Assessment of Na-related soil degradation has usually been carried out in the context of agriculture and soil productivity. Sodic soils pose numerous environmental hazards in agricultural, engineering, and urban settings (Fitzpatrick et al., 1994; Sumner et al., 1998), but at the same time present some opportunities for enhanced carbon sequestration in the soil (Lal, 2001).

18.8.1 Erosion and Suspended Sediments

Sodic soils are susceptible to clay dispersion and surface sealing, which generate runoff flow and cause erosion; posing a serious problem from crop production point of view. However, despite the fact that ~60% or more of the sediments settle out from the runoff water before it reaches a stream or other water body, there is a consensus that the sediments leaving cultivated fields have substantial negative impacts. Results of a recent study (Ghadiri et al., 2007) indicate that large sediment and salt losses can occur in runoff from saline-sodic soils, even at low slopes and from apparently stable soils, with major downstream water quality consequences. Crosson (1985) estimated that the cost of offsite damage from cropped land in the United States exceeded \$1 billion annually. Sediments clog drainage ditches and irrigation canals, and decrease the capacity of water reservoirs, thus increasing maintenance costs. In addition, sediments damage or entirely destroy fish spawning areas. Sedimentation of rivers and streams reduces their capacity to carry water and increases the danger of flooding and consequent damage to property and to

The presence of suspended sediments in water increases its turbidity. Under certain conditions common in sodic soils (high pH and ESP), SOM can dissolve in runoff water and enhance clay dispersion and mobilization (Naidu et al., 1993a) and, hence, increase water turbidity. Turbid waters are less attractive for recreational activities and allow less sunlight to pass through, thus negatively affecting aquatic productivity. In addition, turbid water, which is denser than clean water, is more costly to pump. High turbidity in water bodies used for domestic consumption leads to extra costs in purification. Finally, turbid water increases the wear and tear and maintenance costs of equipment through which it passes.

Enhanced clay dispersivity associated with sodic condition in the soil can lead to surface and subsurface erosion processes such as piping and tunneling. The creation of these subsurface channels may result in the formation of deep gullies that further enhances erosion. Records show that tunnel erosion that occurs in many parts of the world, but mainly in kaolinitic and illitic soils (Sumner et al., 1998), requires readily dispersible clay for its development.

18.8.2 Salinity and Pollutants

Sodic soils commonly contain high levels of salts that are transferred to nearby water bodies at a relatively fast rate when the soil is cultivated (Fitzpatrick et al., 1995). In Australia and America, high saline-sodic watertables contribute significantly to the salt load of rivers (Sharma and Williamson, 1984). In addition, sodic soils require proper drainage systems to remove water, which is much more saline than the irrigation water. When this drainage water enters surface water, its quality deteriorates, rendering it at times unsuitable for further use in irrigation, livestock watering or cities (Sumner et al., 1998).

In addition to the excessive salt load in sodic soils originating from pedogenic processes and irrigation with saline-sodic waters requiring disposal, there is a salt accumulation resulting from soil reclamation. Most reclamation activities require the addition of Ca salts (e.g., gypsum). In the soil, following exchange reactions, the salts become largely Na salts. In general, Na salts dissolve readily and are easily displaced downward into soil strata and groundwater beneath the irrigated field. Extensive reclamation can also cause shallow saline watertables that often require drainage. The saline drainage water ends up at surface water bodies, increases their salinity, and reduces their value. Hence, reclamation of sodic soils may have some negative environmental consequences that should be weighed carefully when planning and execution of reclamation activities are considered.

Transport of various contaminants by soil colloidal materials whether to ground or surface water bodies in runoff is a serious environmental hazard. Metals that usually are fairly immobile in soil and have strong affinity for soil colloids move together with the mobile colloids (Kaplan et al., 1993). Similarly, insoluble pesticides, herbicides, and some nutrients (e.g., P) have a high affinity for soil colloids and can thus be transported with suspended solids to adjacent water bodies and groundwater. The increased concentration of suspended colloids in runoff water due to sodic conditions greatly increases the danger of higher than permitted loadings of these pollutants in ground and surface water bodies.

18.8.3 Carbon Sequestration

Sodic soils have lost over the years a large fraction of their original carbon (C) pool (Lal, 2001). The magnitude of the loss may range between 10 and $30\,\mathrm{Mg}$ C ha⁻¹, depending on the antecedent pool and the severity of degradation (Qadir et al., 2006). Amelioration of sodic soils may enhance C accumulation in the soil in both organic and inorganic forms.

With respect to sequestration of C in an organic form, cultivation of sodic soils with suitable crops, shrubs, or trees can lead to the accumulation of organic C in the soil through biomass production (Garg, 1998; Kaur et al., 2002). Qadir et al (2007) report that estimates from various field studies on alkali soils suggest that various land-use systems consisting of a number of grasses and trees can sequester organic C in the range of 0.2–0.8 Mg C ha⁻¹ year⁻¹.

Sodic soils are commonly found in arid and semiarid regions. Soils in these regions generally contain large pools of primary (lithogenic) and secondary (pedogenic) inorganic carbonates (Lal, 2002). Dissolution of the carbonates at the root zone could result from the buildup of high pCO $_2$ (root respiration and decomposition of organic matter) or by acidic root exudates. The resultant HCO $_3$ ⁻ can then be leached, especially under irrigation management, down the soil profile, and its subsequent precipitation is a possible pathway for C sequestration in an inorganic form. Wilding (1999) estimated that C sequestration through this mechanism ranges between 0.25 and 1.0 Mg C ha⁻¹ year⁻¹.

18.9 Conclusions

Many soils world wide contain sodium at levels that may negatively affect soil physical properties, crop production, and the environment. The area occupied by sodium-affected soils is expected to grow due to the increased use of poor quality soils and water for agricultural activities. However, use of such soils for crop production is also expected to increase with the growth of world population. Hence, careful and detailed assessments of the effects cultivation of sodic soils may have on- and off-site, will become essential.

Sodium-related soil degradation and loss of productivity are, to a certain degree, reversible as sodic soils can be reclaimed through physical interventions (e.g., specific tillage operations), chemical treatments or vegetative remediation. The latter option is effective mainly in moderately sodic conditions and has several economic, environmental, and agronomic advantages; but the remediation process is slow and the presence of a source of Ca in the soil (e.g., calcite) is required. Use of chemical treatment leads to fast soil amelioration and is preferable under extreme sodic conditions. A holistic approach for sustainable amelioration and use of sodic soils that takes into consideration, in addition to agricultural aspects, economic, social, and environmental issues, should be adopted in order to maintain the productivity of these soils for many years.

With a better understanding of sodic soils' behavior coupled with a greater knowledge of the management practices needed to handle such soils, and with the growing demand for food production, it is time to consider sodic soils as a useful resource rather than a problem. Amelioration of these soils will not only increase agricultural productivity but will also carry some environmental benefits such as decrease of desertification and soil erosion, and mitigation of greenhouse effects via C sequestration.

19.1 Introduction

Although soils are normally thought of as being readily wettable by rainfall or irrigation, it is not uncommon for soils to behave in a water-repellent (hydrophobic) manner (Figure 19.1). This resistance of soils to wetting when in contact with water can persist from as little as a few seconds to, in extreme cases, months (e.g., King, 1981; Dekker and Ritsema, 1994; Doerr and Thomas, 2000). Water-repellent behavior is typically confined to the organically enriched upper few centimeters or decimeters of the soil and tends to be both spatially and temporally highly variable. It can develop when soil moisture falls below a critical threshold and often disappears after prolonged wet periods (Dekker et al., 2001).

Jamison (1946) was arguably the first to demonstrate that soil water repellency reduced crop productivity, and since the 1980s the use of wetting agents in horticulture and turfgrass industries (Cisar et al., 2000), or clay additions or advanced irrigation techniques in agriculture (Blackwell, 2000), has become a common amelioration measure. Soil water repellency is also viewed as a key factor in enhanced hydrological and erosional hillslope and catchment responses that are often observed following wildfire (Shakesby and Doerr, 2006).

During the last two decades, it has become increasingly apparent that soil water-repellent behavior is relatively common. It has been reported for soils ranging from coarse- to fine-textured, from land uses including plowed cropland, pasture, shrubland, and a wide range of forest types, and under climates ranging from seasonal tropical to subarctic (e.g., Wallis and Horne, 1992; Bauters et al., 2000a; DeBano, 2000; Doerr et al., 2000; Doerr et al., 2006a). Its intensity can vary considerably from extremely high, as observed under many eucalypt species (e.g., Keizer et al., 2005; Doerr et al., 2006b), to being so slight

that it is detectable only with a purpose-built micro-infiltrometer (Hallett and Young, 1999). The view that water repellency in soils is the norm rather than the exception, with its intensity being variable (Wallis et al., 1991), has now become widely accepted.

19.2 Origin and Classification

19.2.1 Fundamental Principles Underlying Water Repellency

Over a wettable (i.e., hydrophilic) surface, water will spread in a continuous film, whereas over a hydrophobic surface, it "balls up" into individual droplets. If the hydrophobic surface is a porous medium like sand or soil, water infiltration is inhibited and the surface is considered to exhibit water repellency (Figure 19.1). The affinity between water and solid surfaces originates from mutually attractive forces (adhesion) and the attraction between the water molecules within the liquid (cohesion). In principle, interfacial tensions between the three phases, that is, the liquid (water), a solid, and vapor (air), can affect water repellency (DeGennes et al., 2003). For the sake of simplicity, however, this chapter will deal only with the liquid and solid surface tensions, the underlying principles of which are briefly considered here.

A water molecule comprises an oxygen atom with a partial negative charge and two hydrogen atoms with a partial positive charge. The hydrogen and oxygen atom bonds are positioned 105° apart, giving the water molecule a strongly dipolar structure (Parker, 1987). The attraction of these positive and negative ends causes water molecules to form aggregates, held together by hydrogen bonds. Water adheres to most natural solid surfaces because their positively or negatively charged ions attract the

FIGURE 19.1 Water drops resting on a highly repellent sandy soil. (Photo courtesy of Erik van den Elsen.)

negative or positive ends of a water molecule, respectively. The dipole character of water, however, also results in a comparatively strong force counteracting the attraction to charged surfaces. Within a liquid, the net force acting on an individual molecule is zero as it is surrounded by other molecules and their forces. When a liquid is in contact with air, however, no similar molecules exist beyond the surface of the liquid to oppose the attraction exerted by the molecules within the liquid. Consequently, the surface molecules experience a net attractive force toward the interior, which promotes the reduction of the surface area of water. Thus, if opposing forces are minimal, liquids will assume a spherical shape (i.e., that of a droplet). To enlarge the surface of a liquid, work is necessary. This work is related to the surface tension (γ) or surface free energy of the liquid. Most liquids have surface tensions between 20 and 40 N m \times 10⁻³ at 20°C, but that of water is comparatively high at 72.75 N m \times 10⁻³ (Parker, 1987). The same principle applies to solid surfaces, although their nature inhibits deformation into a spherical shape. The surface tension of solids therefore leads to lateral forces at the surface. Hard solids such as soil minerals can have surface tensions between 500 and 5000 N m \times 10⁻³, increasing with hardness and melting point (Zisman, 1964). For water to spread on a solid, the adhesive forces between them must exceed the cohesive forces within the body of water. Thus, surfaces with a surfacefree energy >72.75 N m \times 10⁻³ attract water and are therefore hydrophilic. The higher the surface tension of the solid, the stronger the attraction. All principal soil minerals have a much higher surface tension than water and are therefore hydrophilic (Tschapek, 1984), whereas soft organic solids, such as waxes or organic polymers can exhibit γ values below 72.75 N m \times 10⁻³ and are thus hydrophobic (Zisman, 1964).

19.2.2 Origin of Water Repellency in Soils

The wettability of a flat surface is determined by the property of its outermost molecular layer. Thus, in principle, a single layer of hydrophobic molecules can render a hydrophilic mineral surface hydrophobic (Zisman, 1964), although in practise, hydrophobic compounds may be absorbed to soil mineral surfaces as globules rather than uniform monolayers (Cheng et al., 2008). The amount of hydrophobic compound required to induce water repellency in soil is nevertheless very small. For example, Ma'shum et al. (1988) induced severe water repellency in 1000 g of medium-sized sand using only 0.35 g of hydrophobic compound. Soil water repellency can also be caused by the presence of hydrophobic interstitial matter. If hydrophobic particles are present in the pore spaces of a hydrophilic matrix, the wettability of the composite material is reduced. For example, severe water repellency has been induced by intermixing as little as 2%–5% by weight of solid organic matter to wettable sand (McGhie and Posner, 1981).

When considering the water repellency of textured media (such as soils) compared to flat surfaces, it is important to recognize the effect of surface roughness and morphology. When water comes in contact with a rough granular surface, a fraction of the water surface will be in contact with solid material, with the remainder being in contact with the air between granules. Air is very hydrophobic and a granular surface can therefore become substantially more water repellent than a flat surface with identical surface chemistry. This phenomenon has been described as "super-hydrophobicity" when the contact angle between the surface and a water droplet exceeds 150°, and is perhaps better known from other biological surfaces such as the lotus leaf, but its underlying principles are also considered to apply to soils (McHale et al., 2005).

The biological origin of hydrophobic compounds in soils is undisputed. Such compounds are naturally abundant in the biosphere and may be gradually released into the soil, for example, as root exudates (Dekker and Ritsema, 1996; Doerr et al., 1998), from soil fauna fungi or microbes (Hallett and Young, 1999; Schaumann et al., 2007), or directly from decomposing organic matter (McGhie and Posner, 1981). Depending on vegetation cover present and soil temperatures reached, a rapid release or redistribution of hydrophobic compounds often accompanies the burning of vegetation, leading to a distinct hydrophobic layer at the soil surface or at some depth in the soil profile (DeBano et al., 1976; Doerr et al., 2006b).

The specific types of compounds suggested to be a cause of soil water repellency include alkanes, fatty acids and their salts and esters, and other related compounds such as phytanes, phytols, and sterols (Ma'shum et al., 1988; Roy et al., 1999; Franco et al., 2000; Horne and McIntosh, 2000; Atanassova and Doerr, 2010). The presence of these compounds, however, does not necessarily lead to the expression of water repellency in soils. It has been demonstrated that comparable amounts of such compounds occur also in wettable soils (Doerr et al., 2005; Morley et al., 2005). It has been suggested that these compounds only cause hydrophobicity when they form a specific molecular arrangement (Roy and McGill, 2000; Morley et al., 2005), which in turn is influenced by soil physical and chemical properties (Doerr et al., 2000; Graber et al., 2009).

Soil Water Repellency 19-3

19.2.3 Measurement and Classification of Soil Water Repellency

There are a number of techniques for measuring and classifying soil water repellency (see Wallis and Horne, 1992; Hallett and Young, 1999; Letey et al., 2000; Bachmann et al., 2003). One of the most common methods, the "Water Drop Penetration Time" (WDPT) test (Van't Woudt, 1959), is briefly described here. It involves placing droplets of distilled water onto a sample surface and recording the time for their complete infiltration (Figure 19.1). This test, which can be carried out on undisturbed soil surfaces in the field or on disturbed and typically air-dried bulk samples in the laboratory, broadly determines how long water repellency persists in the contact area of a water droplet. It is particularly relevant to estimating the likely response of a soil surface to rainfall or irrigation. This persistence or stability of water repellency is usually somewhat, but not always, well related to the apparent surface tension (i.e., the severity of water repellency) of soil (Dekker and Ritsema, 1994; Doerr, 1998; Scott, 2000). Water repellency severity will determine how strongly a droplet initially balls up when in contact with the soil and can be determined indirectly by contact angle or critical surface tension measurements (see Letey et al., 2000). Contact angles can, however, change rapidly if the persistence of water repellency is low. The apparent surface tension of the soil is particularly relevant when modeling flow processes through the soil matrix. When performing tests in the field or the laboratory, it is important to consider that in situ testing in the field reflects the water repellency measured at a distinct point on a given surface, whereas laboratory testing of bulk samples reflects the apparent water repellency of mixed soil material over the depth and area that has been sampled. Field and laboratory data may therefore not be directly comparable. Furthermore, it has been shown that the physical disturbance to the soil caused by sampling can substantially increase or decrease water repellency (Graber et al., 2006).

Perception of what constitutes high or low level water repellency *persistence* varies widely. To distinguish between wettable and water-repellent soils, an arbitrary WDPT threshold of 5 s (Bisdom et al., 1993; Table 19.1) has been used widely, although considerable effects on water movement at the centimeter-scale have been shown to be caused by lower, so called subcritical, levels of repellency (Hallett et al., 2004). WDPT values found in the literature are generally presented in categories rather than distinct values and are not always directly comparable because, for practical reasons, this test is often terminated well before droplet penetration occurs. In many studies to date, WDPTs exceeding 1 h have been recorded (= classed as extreme persistence; Table 19.1), but *persistence* can in some cases reach levels such that even ponding water may not infiltrate for periods exceeding 1 month

(Doerr and Thomas, 2000). Although the aforementioned laboratory tests allow a general classification of soils according to water repellency *persistence* and *severity*, these measurements do not always relate well to the actual wetting behavior of field soils for which infiltrometer measurements or rainfall simulations may provide additional insight (Doerr et al., 2006a).

19.3 Occurrence of Soil Water Repellency

19.3.1 Distribution of Water Repellency

Soil water repellency has been reported in well over 1000 studies, which have focused on soils ranging from coarse- to fine-textured, land uses including plowed cropland, pasture, shrubland, and a wide range of forest types, and from climates ranging from seasonal tropical to subarctic (e.g., Wallis and Horne, 1992; Bauters et al., 2000a; DeBano, 2000; Doerr et al., 2000, 2006a). Although the occurrence of soil water repellency is normally not assessed within general soil surveys and hence little is known about its wider distribution, the view that it is the norm rather than the exception, with its degree being variable (Wallis et al., 1991), is now widely accepted. Regional-scale surveys in The Netherlands (Dekker et al., 2000) and the United Kingdom (Doerr et al., 2006a) indicate that water repellency is particularly common under grass, shrub, and conifer forest land. There are also many reports of high levels of water repellency being naturally common under a range of eucalypt species (e.g., Keizer et al., 2005; Doerr et al., 2006b). Furthermore, it is well established that peat, once dried out, can become highly water repellent (Fuchsmann, 1986). Coarser-scale studies suggest, for example, that in the Netherlands, 75% of the crop- and grassland exhibits water repellency (Dekker and Ritsema, 1994) and that in southern Australia 5 million hectares of land are affected, leading to production losses of up to 80% in Australian agriculture (Blackwell, 2000). In some sectors, such as horticulture and sports turf (e.g., golf greens, playing fields), wetting agents are widely used to increase soil wettability (e.g., Cisar et al., 2000). Where recycled wastewater is used for crop irrigation, it has recently been recognized that this practise can impart water repellency and result in uneven water distribution (Wallach and Graber, 2007).

A substantial body of research has also focused on the presence of water repellency following wildfire where it is thought to play a key role in the often enhanced hydrological and erosional responses of burnt terrain. In such environments, soil water repellency is often considered to be fire-induced although it is clear that it can also be present without the influence of burning (Shakesby et al., 1993; DeBano, 2000; Doerr et al., 2009).

TABLE 19.1 Water Drop Penetration Time (WDPT) Class Intervals in Seconds (Upper Limit) and Associated Repellency *Persistence* Rating

Persistence rating ^a	_		Slight		S	trong		Severe		Extr	eme	

^a Based on Bisdom et al. (1993).

The heat generated by burning, in addition to redistributing and concentrating the naturally occurring hydrophobic substances in the soil, is also thought to make these compounds more hydrophobic by pyrolysis and conformational changes in their structural arrangement. Laboratory studies have shown that soil water repellency is intensified when soil temperatures reach 175°C-270°C, but is destroyed at temperatures above 270°C-400°C. The duration of heating can also affect the degree of soil water repellency with longer heating times reducing the temperature at which these changes occur (e.g., DeBano et al., 1976; Doerr et al., 2004). When there is insufficient oxygen, the temperature at which soil water repellency is destroyed may rise to 500°C-600°C (Bryant et al., 2005). Apart from the influence of burning conditions, factors such as the type and quantity of vegetation present or soil properties such as organic matter characteristics, clay content or mineralogy can influence the effects of fire on water repellency (Arcenegui et al., 2007; Mataix-Solera et al., 2008). The effects of burning on soil water repellency can therefore be highly variable, with fire potentially inducing water repellency in soils that were largely nonrepellent, or either enhancing or reducing pre-existing water repellency.

19.3.2 Factors Affecting Water Repellency Occurrence

Apart from the major factors linked to water repellency occurrence such as vegetation type and fire occurrence outlined above, there are a number of other environmental or soil specific factors that can affect water repellency. Coarse-textured soils are generally thought to be more susceptible to the development of soil water repellency than finer-textured ones. This is generally attributed to their relatively smaller particle surface area, which requires less organic material to generate a hydrophobic coating (DeBano, 2000). Hence, clay additions have been used successfully to reduce repellency in sandy soils (Blackwell, 2000; Figure 19.2). The specific mineralogy of the clay applied is of importance here (McKissock et al., 2000; Lichner et al., 2006) and the

FIGURE 19.2 Dispersive clay is added to highly water-repellent soil on a farm in southern Australia to improve soil wettability. (Photo courtesy of S. Doerr.)

aforementioned soil surface topography effect (super-hydrophobicity; Section 19.2.2) may also be of relevance. Finer textured soils, however, have also been reported to exhibit high levels of water repellency (Dekker and Ritsema, 1996). This is thought to arise when substantial amounts of hydrophobic organic matter are present (DeBano, 2000; Doerr et al., 2000).

Water repellency appears to be more common in acidic than in calcareous soils (Mataix-Solera et al., 2007). The more wide-spread occurrence of acidic soils may be a compounding factor here. However, it is also thought that the lower fungal activity and less organic matter content typical of neutral or alkaline soils make them less prone to water repellency development (Hallett and Young, 1999; Mataix-Solera et al., 2007). Furthermore, there is evidence that the pH-related availability and relative abundance of proton active sites in the soil can be another factor affecting water repellency (Diehl et al., 2010). Thus, for example, high pH treatments have been used to reduce water repellency on golf greens (Karnok et al., 1993).

Perhaps the most critical factor affecting the occurrence of water repellency in soils that are prone to water repellency is soil moisture. As outlined earlier, water repellency can be temporally highly variable. Depending on its level of persistence, it tends to disappear after prolonged contact with water and typically reappears when soil moisture falls below a critical threshold (Dekker et al., 2001). A fundamental factor thought to be critical in this "switching" behavior is the specific molecular arrangement of the organic coating on soil particle (or soil pore wall) surfaces. It is thought that at low soil moisture contents, the hydrophobic ends of the organic molecules will tend to be oriented away from the surface toward the soil pore space, imparting water repellency. During prolonged water contact, these molecule ends "fold" onto the particle surface, thereby exposing more hydrophilic areas and ultimately making the soil wettable (Tschapek, 1984; Roy and McGill, 2000; Morley et al., 2005). Whether or not this is the main reason for the "switching behavior," several studies have shown that water repellency is not present above a critical soil water threshold. In sandy soils, this threshold can be at a water content of a few volume percent (Dekker et al., 2001; Täumer et al., 2005), but for finer-textured soils, thresholds in the region of 20%-30% have been reported (Doerr and Thomas, 2000; Doerr et al., 2006a). What happens below this threshold is not entirely clear. Although water repellency typically recovers when soils dry out, this effect may be delayed (Crockford et al., 1991; Leighton-Boyce et al., 2005) and some soils may remain wettable after drying (Doerr and Thomas, 2000). This makes the prediction of water repellency occurrence particularly challenging.

19.4 Hydrological and Geomorphological Effects of Soil Water Repellency

The primary hydrologic and erosional effects of soil water repellency include: (a) lower infiltration rates and a corresponding increase in the likelihood and amount of infiltration-excess (Hortonian) overland flow, (b) more spatial variability in infiltration and soil moisture fluxes, causing an uneven distribution of

Soil Water Repellency 19-5

soil moisture, (c) increased surface erosion aided by the increase in overland flow, and (d) enhanced susceptibility to wind erosion due to drier soil conditions and reduced cohesion of soil particles. The reduction in infiltration can also have secondary effects, such as hindering the germination and growth of vegetation, which can prolong fire impacts on runoff and erosion rates (see reviews by DeBano, 2000; Doerr et al., 2000; Shakesby et al., 2000; Shakesby and Doerr, 2006).

19.4.1 Hydrological Effects of Water Repellency

The most frequently reported effect of soil water repellency is reduced infiltration (e.g., Van Dam et al., 1990; Imeson et al., 1992; Doerr et al., 2003) and thus increased overland flow (e.g., McGhie and Posner, 1980; Crockford et al., 1991; Witter et al., 1991). For example, the infiltration capacity of a water-repellent soil was found to be 25 times lower than for a similar soil rendered hydrophilic by heating (DeBano, 1971). Owing to the reduced surface tension of the soil pore walls, a water-repellent soil matrix will have a positive soil water potential. This effectively leads to a capillary depression effect illustrated in Figure 19.3. Infiltration into a relatively dry water-repellent soil matrix will therefore only occur if a ponding depth (hydraulic head; entry pressure) sufficient to exceed the positive soil water potential is reached. The necessary ponding depth may decrease with time if water repellency decays during water contact. These factors acting in combination usually result in infiltration rates increasing during rainfall. This contrasts with "normal" soil behavior, where infiltration rates decrease over time (Figure 19.4; Letey et al., 1962; Kirkham and Clothier, 2000). The lack of capillary rise in water-repellent topsoil, on the other hand, leads to reduced evaporation from the subsoil, which may be advantageous to plant communities in drier regions (Doerr et al., 2000).

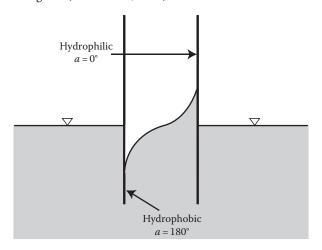

FIGURE 19.3 Shape of the meniscus of water between a hydrophilic and a hydrophobic plate with liquid-solid contact angles of 0° and 180°, respectively. (Adapted from Bauters, T.W.J., T.S. Steenhuis, D.A. DiCarlo, J.L. Nieber, L.W. Dekker, C.J. Ritsema, J.-Y. Parlange, and R. Haverkamp. 2000b. Physics of water repellent soils. J. Hydrol. 231–232:233–243.)

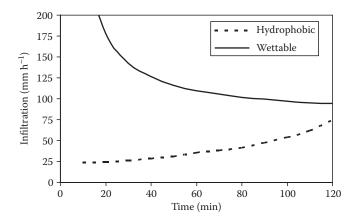

FIGURE 19.4 Infiltration rates into wettable and water-repellent soils. (Adapted from Letey, J., J. Osborn, and R.E. Pelishek. 1962. The influence of the water-solid contact angle on water movement in soil. Bull. Int. Assoc. Sci. Hydrol. 3:75–81.)

On a water-repellent soil surface in the field, rainwater will pond and, if rainfall is sufficient and surface detention exceeded, Hortonian (infiltration-excess) overland flow will occur. The frequency of "gaps" through the water-repellent layer (such as structural or drying cracks, root holes and burrows, and patches of wettable or less repellent soil) will then determine whether overland flow is widespread or only local (Figure 19.5a). Under some conditions, for example, where intense soil heating during a wildfire has destroyed water repellency in the top few centimeters of the soil (see DeBano, 1971), rainfall infiltrating such a topsoil may pond above the water-repellent layer (Figure 19.5b). The commonly observed temporal variability of water repellency also needs to be considered here. Thus reductions in infiltration capacity and increases in overland flow can be expected to be most pronounced following prolonged dry periods, when water repellency tends to be most severe. For example, Burch et al. (1989) recorded infiltration capacities in Australian eucalypt forest of 0.75-1.9 mm h⁻¹ when dry, but 7.9-14.0 mm h⁻¹ when wet. In many areas, water repellency-linked overland flow may therefore be confined to storm events following dry weather (Sevink et al., 1989; Walsh et al., 1994). The rapid response of Hortonian overland flow in a water-repellent soil following dry weather contrasts sharply with the muted overland flow in moderately wet weather, when soils are generally wettable (Jungerius and De Jong, 1989; Ferreira et al., 2000).

Another common observation in soils prone to water repellency is enhanced preferential flow, which is the concentrated vertical movement of water via preferred pathways through the soil. It may originate for a variety of reasons such as cracks and biopores, textural discontinuities, and unstable wetting fronts, which may result, for example, from soil layering and air entrapment (Ritsema et al., 1993). In stony, water-repellent soils, water movement may be facilitated along sand-stone interfaces and preferential flow may take place where there are contiguous stone-to-stone connections (Urbanek and Shakesby, 2009). Although not restricted to water-repellent soils, repellency can be particularly effective at preventing or

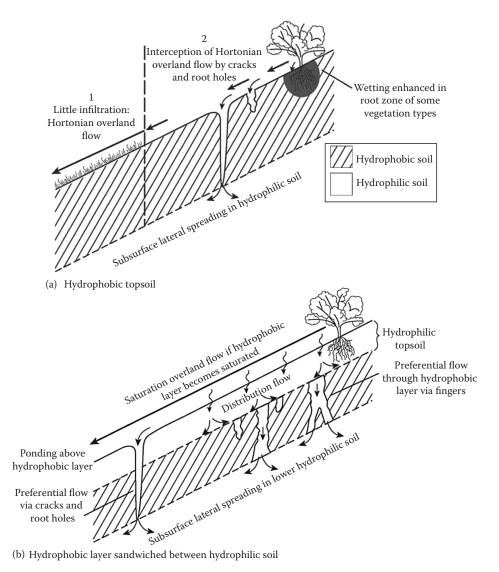

FIGURE 19.5 Schematic illustration of possible hydrological responses of soil with (a) a water-repellent layer located on the surface, and (b) a repellent layer sandwiched between wettable soil. (Adapted from Doerr, S.H., R.A. Shakesby, and R.P.D. Walsh. 2000. Soil water repellency, its characteristics, causes and hydro-geomorphological consequences. Earth Sci. Rev. 51:33–65. Copyright 2000, with permission from Elsevier.)

hindering downward water movement, directing it into structural or textural preferential flow paths (Figure 19.5a and b) and creating an unstable irregular wetting front (Figure 19.6). Consequently, soils may not wet completely with the passage of a wetting front (DeBano, 1971), and water may be channeled via biopores (Shakesby et al., 2007), cracks, and pipes, thereby bypassing the water-repellent soil matrix (e.g., Burch et al., 1989; Ferreira et al., 2000). Walsh et al. (1995) considered that macropores and cracks could explain why even large storms produced little overland flow for extremely water-repellent mature pine and eucalypt forest soils in Portugal. Irrespective of the dominance of enhanced overland or subsurface flow, the reduced soil water storage capacity in catchments affected by soil water repellency is likely to increase flooding particularly in cases where long dry periods are followed by large rainstorm events. This situation can be further exacerbated following the

removal of a protective vegetation and litter cover by clearance or fire (Figure 19.7).

On a grass-covered sandy soil in Holland, Ritsema et al. (1993) used tracers to record distribution flow within a thin (<2.5 cm) wettable topsoil, which supplied water via columns of less repellent soil (preferential flow paths) in an otherwise extremely repellent layer to the wettable subsoil, where the water spread laterally. This has been termed "fingered flow" (Ritsema and Dekker, 1994). The fingers formed only after dry weather when soil moisture levels in the sandy, repellency-prone layer were below a "critical" value of 4.75% (vol.). The fingers ranged from 10 to 50 cm in diameter (expanding in wetter weather), and were the sole means of water transport for several hours during sustained rainfalls. Such fingers have been shown to recur at the same places in successive storms following intervening dry weather, possibly aided by preferential leaching of hydrophobic

Soil Water Repellency 19-7

FIGURE 19.6 Irregular wetting front and preferential flow pathways in a hydrophobic sandy agricultural soil in Western Australian. (Photo courtesy of R. Shakesby.)

FIGURE 19.7 Enhanced overland flow during intense rain in burnt eucalypt forest terrain in the Victorian Alps, south-east Australia in 2003. (Photo courtesy of Rob Ferguson.)

substances from the finger pathways (Ritsema et al., 1998). In a study in Germany, wet and adjacent dry areas were seasonally persistent in a grass-covered and partially water-repellent soil (Täumer et al., 2005). Preferential flow in general is thought to be reinforced by soil water hysteresis between wetting and drying phases, a feature of wettable soils but more pronounced in water-repellent ones (Ritsema et al., 1998).

Water repellency-induced fingered flow can lead to considerable variations in water content in an initially repellent soil such that zones of very dry soil can abut directly against zones of wet soil. For example, Dekker and Ritsema (1996) found differences in soil moisture of up to 28% (vol.) between closely spaced samples in both clay and sandy soils (see also Figure 19.6). Such differences do not only result in the widely reported

poor seed germination and plant growth. Any type of preferential flow path formation can also lead to accelerated leaching of surface-applied agrichemicals and an increased risk of surface- and groundwater contamination (Hendrickx et al., 1993; Ritsema et al., 1993).

19.4.2 Effects of Water Repellency on Erosion

In general, the most important way in which soil water repellency can influence erosion lies in its potential for contributing to an increase in the proportion of rainfall going to overland flow. As the amount of overland flow increases, its depth and velocity also increase and with it the ability of the water to detach and transport particles, initially by sheetwash (Shakesby et al., 2000). Then, as the overland flow becomes concentrated into small rivulets, this can initiate rill erosion (Benavides-Solorio and MacDonald, 2005). At a larger scale, convergence of overland flow in concave parts of hillslopes can lead to the formation of gullies, and to downstream channel bank and bed erosion (e.g., Moody and Martin, 2001).

Soil water repellency can also directly affect erosion rates by altering the erodibility of the soil. Laboratory tests have shown that individual water drops falling on a water-repellent soil produce fewer, slower-moving ejection droplets than those on wettable soils, but the splash ejection droplets developed on the former carried more sediment (Terry and Shakesby, 1993). With successive drops, the surface of the water-repellent soil remained dry and noncohesive, and the soil particles continued to be displaced by rainsplash despite the retention of an overlying film of water. In contrast, drops falling on the surface of the wettable soil sealed and compacted it, which increased its resistance to detachment by rainsplash. Aggregate stability, in contrast, has been shown to be higher in water-repellent soils, which may counter the above effect to some degree in soils that exhibit aggregation (Giovannini and Lucchesi, 1983; Mataix-Solera and Doerr, 2004).

At hillslope and watershed scales, the role of soil water repellency in increasing erosion is less certain. Its overall impact is likely to be reduced where areas with macropores or wettable soil patches promote interception of overland flow generated locally on water-repellent areas.

Soil water repellency can also play a role in other forms of erosion. It can enhance wind erosion as a result of reduced soil moisture, which in turn reduces soil particle cohesion and lowers the threshold wind velocity for particle detachment and entrainment (Whicker et al., 2002). Dry ravel (the rapid, dry particle-to-particle sliding of sediment through gravity) is a form of mass movement that is strongly associated with postfire water-repellent conditions, particularly in chaparral vegetation of the western United States (Wells, 1986). Formation of small-scale debris flows related to failure of a saturated layer of wettable soil only a few millimeters thick overlying a subsurface water-repellent zone can occur (Gabet, 2003). The links between larger debris flows and water-repellent soils seem to be less certain (Cannon, 2001).

19.5 Conclusions

Three decades ago, soil water repellency would have been viewed as a curious aberration by many soil scientists, whereas it has now become a widely acknowledged soil property that is typically (i) highly variable spatially, temporally, and in its degree, (ii) common for many types of soils, vegetation covers, and climates, (iii) confined to the top few centimeters or decimeters of soil, (iv) enhanced, but in some cases unaffected or eliminated following fire, depending on the degree of soil heating, and (v) most pronounced under dry conditions, but reduced or absent after prolonged rainfall.

Water repellency has notable, and in some cases, substantial implications for soils. It can lead to reduced seed germination and plant growth, reduced infiltration and evaporation, enhanced overland flow, accelerated preferential flow and increased soil erosion. In many cases, water repellency is naturally induced and perhaps beneficial in terms of plant competition and reduction of evaporative losses from the soil surface. From a soil management perspective, however, there are a number of detrimental impacts including reduced crop performance, ineffective use of irrigation water, enhanced contamination risk via accelerated overland and preferential flow, and increased risk of flooding, soil erosion, and debris flow. These potential impacts need to be considered carefully when managing water-repellent soils.

20.1 Introduction

Wetlands comprise swamps, marshes, fens, peat lands, bogs, potholes, bays, riparian zones, floodplains, and other shallow flooded areas. These areas are located at the interface of terrestrial and aquatic systems and often possess the characteristics of both systems. Wetlands have been estimated to occupy about 2.8×10^6 km² or 2.2% of the earth's surface (Post et al., 1982); however, the areal extent may be as high as 6% (Mitsch, 1994). One reason for this discrepancy probably lies in the difficulty of accurately defining wetlands. Within the conterminous United States, wetlands occupy about 5% of the land surface, and many of these wetlands are among the most productive natural systems. Wetlands are critical components of the biosphere because they provide essential ecological functions including habitat for wildlife, groundwater recharge, shoreline stabilization, flood control, and water quality improvement through biogeochemical transformations. Wetland soils specifically function as sinks and as transformers of nutrients, toxic metals, and organics. Recently, the impact of wetlands on the production/consumption of greenhouse gases (CO₂, CH₄, N₂O, and methyl sulfides) has been realized. A major food crop, lowland rice, is also grown under waterlogged soil conditions that are similar to wetland soils in physical, chemical, and biological properties.

20.2 Definitions

Although the definition of soil primarily focuses on upland soils, it includes those that undergo periodic or continuous flooding. Depending on scientific disciplines and ecosystems, soils

saturated with water are often called flooded, wetland, waterlogged, marsh, paddy, or hydric soils, but no universally accepted definition for wetland soils exists among various groups.

The term "wetland" implies that the lands are located in wet areas. However, defining a "wetland" is often complex and difficult, because of the diversity in types of wetlands, presence of moisture gradients from clearly defined upland areas to aquatic systems, as well as the observation that many wetlands are not permanently inundated. These difficulties have resulted in the propagation of several legal and nonlegal definitions of wetlands. However, most definitions include reference to three major components of wetlands: (1) hydrology (water), (2) organisms (plants and animals), and (3) hydric soil. (US Army Corps of Engineers, 1987).

The following definitions are probably the most often used to describe and delineate wetlands from other ecosystems:

Webster's Collegiate Dictionary Definition: "Land or areas (tidal flats or swamps) containing much soil moisture."

USEPA Definition: "Those areas that are inundated or saturated by surface or ground water at a frequency and duration sufficient to support, and that under normal circumstances do support, prevalence of vegetation typically adapted for life in saturated soil conditions. Wetlands generally include swamps, marshes, bogs and similar areas." This is a regulatory definition of wetlands used by EPA and U.S. Corps of Engineers for administering Section 404 of the Clean Water Act (EPA, 1988).

U.S. Fish and Wildlife Service Definition: "Wetlands are lands transitional between terrestrial and aquatic systems where the water table is usually at or near the surface or the land is covered by shallow water." For purposes of this classification, wetlands must have one or more of the following three attributes:

(1) at least periodically, the land supports hydrophytes predominately; (2) the substrate is predominately undrained hydric soil; and (3) the substrate is nonsoil and is saturated with water or covered by shallow water at some time during the growing season of each year (Cowardin et al., 1979).

National Research Council Definition: "A wetland is an ecosystem that depends on constant or recurrent, shallow inundation or saturation at or near the surface of the substrate. The minimum essential characteristics of a wetland are recurrent, sustained inundation or saturation at or near the surface and the presence of physical, chemical, and biological features reflective of recurrent, sustained inundation or saturation. Common diagnostic features of wetlands are hydric soils and hydrophytic vegetation. These features will be present except where specific physicochemical, biotic, or anthropogenic factors have removed them or prevented their development" (Lewis, 1995).

Reddy and Patrick (1999) Definition: A much broader definition of a wetland is a biologically active soil or sediment in which the content of water in or the overlapping floodwater is great enough to inhibit oxygen diffusion into the soil/sediment and stimulate anaerobic (oxygen free) biogeochemical processes. This definition does not necessarily contain any reference to plants, but biologically active soil or sediment is necessary, which means the presence of an energy source (usually organic matter). We define wetland soils with or without aquatic vegetation.

As can be seen from this list of potential definitions, wetlands are typically limited to areas with a presence of hydrophytic vegetation. At present this definition is most commonly accepted, although there is considerable disagreement on the boundaries of developing wetlands from upland areas.

20.3 Wetland Soils

Wetland soils form in a variety of climates and parent materials. They represent a broad spectrum of morphological properties and taxonomic classes, and can be dominated by inorganic or organic materials. However, wetland soils have in common the condition of prolonged saturation. The term saturation refers to the condition of zero or positive hydraulic head, during which water would flow into unlined auger holes with a high proportion of pore space filled with water. This condition favors certain physical, chemical, biological, and morphological tendencies that help to distinguish wetland soils from their upland counterparts. A detailed discussion of redox phenomena is presented in Chapter 14 of *Handbook of Soil Sciences: Properties and Processes*.

20.3.1 Physical Properties

Saturation causes a number of physical changes in soils, including (1) reduced soil strength as a result of the weakening effect of water on forces binding soil particles. This physical effect can have several consequences: (i) root penetration by wetland plants is made easier and the soil is much easier to manipulate when wet, advantages that rice farmers have exploited for centuries,

and (ii) trafficability of land is much poorer when flooded. (2) increased heat absorption by darkening soil color. Increased water content also increases heat conductivity and stabilizes soil temperate to a more constant value compared to upland soils. Sometimes saturated soils are cooler at the surface as a result of evaporation. In wetlands located in cooler climates, the presence of water may prevent soil temperatures from going below 0°C. (3) decreased soil bulk density (weight of dry soil per unit volume) as a result of flooding. Typical bulk densities of upland and wetland soils range between 0.3–1.5 and 0.1–1.0 g cm⁻³, respectively, with low values typically observed in organic soils. This is due to high water absorption capacity of organic matter and destruction of soil aggregates.

20.3.2 Chemical and Biological Properties

Wetland soil chemistry is strongly influenced by the chemical reduction normally associated with saturation. Upland soils can be transformed into wetland soils as a result of excessive rainfall, rising water table, and high oxygen demand in the soil. Under these conditions, oxidized chemical species are chemically reduced as a result of abiotic and biotic processes. Similarly, improving the drainage of wetland soils can result in the oxidation of many of the reduced compounds in the soils either by chemical or biochemical reactions (Figure 20.1). The relative abundance of oxidized and reduced chemical species is, therefore, an indicator of the degree of wetness or anaerobic conditions in soils. The elements Fe and Mn are soil components that are particularly influenced by oxidation and reduction. Examples of Fe-bearing minerals likely to be most stable under the reduced conditions of wetlands include pyrite (FeS₂), siderite (FeCO₃), and vivianite (Fe₃(PO₄)₂ 8H₂O). The Fe in these minerals is in reduced (Fe(II), "ferrous") form. The dominant form of Fe under aerobic conditions is Fe(III) or "ferric" form. Common Fe minerals in relatively oxidized soil environments include goethite and lepidocrocite (both FeOOH), and hematite (Fe₂O₃).

Redox potential is used to measure the intensity of soil anaerobic conditions. Analogous to pH (which measures H⁺ activity),

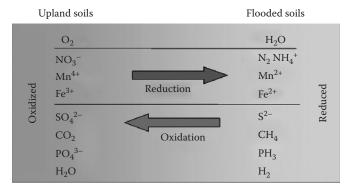

FIGURE 20.1 Predominant forms and changes of key biogeochemical compounds found under aerobic and anaerobic conditions. (From Reddy, K.R., and R.D. DeLaune. 2008. Biogeochemistry of wetlands: Science and applications. CRC Press, Boca Raton, FL.)

redox potential (Eh) measures electron (e⁻) activity in the soil. Redox potential is defined as the tendency of a pair of chemical species to undergo a transfer of electrons, with one species accepting electrons (reduction) and the other donating electrons (oxidation). Redox reactions involve oxidants, reductants, protons, and electrons, as shown below:

$$a(Oxidants) + bH^{+} + ne^{-} = c(Reductants) + dH_{2}O$$
 (20.1)

The following Nernst equation shows the thermodynamic relationship between redox potential (Eh) and the oxidation–reduction reactions:

$$Eh = E^{o} - \frac{RT}{nF} ln \frac{[Reductants]^{c}}{[Oxidants]^{a} [H^{+}]^{b}}$$
 (20.2)

where

Eh is redox potential

E° is the standard electrode potential

R is the gas constant (8.314 J K⁻¹ mol⁻¹)

T is the absolute temperature (K)

F is the Faradays constant $(9.65 \times 10^4 \text{ C mol}^{-1})$

n is the number of electrons transferred

Brackets denote the activity of chemical species in mol L-1

Redox reactions are critical because they regulate the fate of many chemical constituents in wetlands. The Eh values of wetland soils range from +700 to -300 mV (Figure 20.2). Negative values represent high electron activity and intense anaerobic conditions typical of permanently waterlogged soils. Under these conditions, there is a low potential for transfer of electrons between oxidized and reduced species, due to lack of oxidized species, such as oxygen. Positive values represent low electron activity and aerobic conditions or moderately anaerobic conditions typical of wetlands in transition zone. Under these conditions, there is a greater potential for electron transfer, due to the presence of oxidized species such as oxygen, nitrate, and oxidized forms of Fe and Mn.

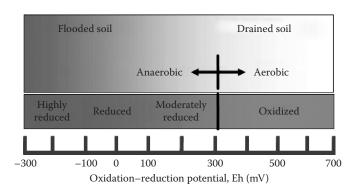

FIGURE 20.2 Association between oxidation–reduction potential and terms used to describe the degree of reduction in a range of flooded and drained soil conditions. (From Reddy, K.R., and R.D. DeLaune. 2008. Biogeochemistry of wetlands: Science and applications. CRC Press, Boca Raton, FL.)

An important redox-related process in wetland soils of marshes involves the formation and potential transformation of the mineral pyrite (FeS₂). Saltwater marsh soils tend to have neutral pH and to support salt tolerant plants (Ponnamperuma, 1972). Pyrite formation occurs as a result of reduction of SO_4^{2-} contained in seawater, high concentrations of Fe(II) in the sediments, and rapid accumulation of organic matter that promotes reduction reactions.

$$CH_2O_{(\text{organic matter})} + H_2O \rightarrow CO_2 + 4H^+ + 4e^-$$
 (20.3)

$$Fe(OH)_3 + e^- + H^+ \rightarrow Fe(OH)_2 + H_2O$$
 (20.4)

$$SO_4^{2-} + 6e^- + 8H^+ \rightarrow S^0 + 4H_2O$$
 (20.5)

$$S^{o} + 2e^{-} + 2H^{+} \rightarrow H_{2}S$$
 (20.6)

$$Fe(OH)_2 + H_2S \rightarrow FeS + 2H_2O$$
 (20.7)

$$FeS + S^{\circ} \rightarrow FeS_2(pyrite)$$
 (20.8)

The drainage of pyritic marsh soils poses an environmental problem, because oxidation of pyrite to ferric hydroxide and sulfuric acid results in severe acidity (to pH less than 2) and dissolution of metal-bearing soil minerals. Bacteria involved in oxidizing FeS₂ are *Thiobacillus ferrooxidans* and *Thiobacillus thiooxidans*.

The chemical and biological processes of wetland soils are strongly mediated by influences and adaptations of the living communities, as exemplified by the redox processes discussed above. The low oxygen environment typical of wetlands inhibits aerobic microbial activity while stimulating activity of facultative and obligate anaerobes, and favors growth of hydrophytic vegetation adapted to living under anaerobic conditions. The presence and types of wetland and aquatic vegetation reflect the degree of soil wetness and intensity of anaerobic conditions.

20.3.3 Organic Soils

Soils vary greatly in their natural organic matter content. However, organic matter tends to accumulate in wetland soils to a greater extent than upland soils because of a high rate of production relative to the rate of decomposition (Mausbach and Richardson, 1994). Thick, dark, organic rich surface layers consisting of slightly to highly decomposed plant remains are therefore common for wetland soils. If these organic rich layers are thick enough such that they essentially comprise the greatest portion of the soil zone, they are referred to as organic soils. The distinction between organic and mineral soils is an arbitrary one, in that depth and organic C content must be specified by a soil taxonomic system. The United States Department of Agriculture (USDA) soil taxonomy (Soil Survey Staff, 1999)

specifies an order of organic soils, Histosols, which is defined as meeting specific depth requirements (in most cases, 40 cm or more) of organic soils material. Organic soil material, in turn, must contain at least 12% organic C if no clay is present, and up to 18% if 60% clay is present (i.e., proportional increase in organic C requirement with increasing clay content). If a layer consisting of organic soil material is thick, but not thick enough to qualify as a Histosol, then it may meet the criteria for a Histic Epipedons ("epipedon" refers to a diagnostic surface or near surface horizon as defined within the USDA soil taxonomic system). Both Histosols and Histic Epipedons are, with some exceptions (e.g., organic matter overlying shallow bedrock), mainly restricted to wetlands. Most organic soils are formed from the accumulation of detritus from hydrophytic vegetation, and transformations of this material into stable humic substances. The organic matter in organic soils is generally most highly decomposed near the soil surface.

The three most extensively occurring suborders of Histosols are distinguished based on the amount of identifiable plant material:

- Saprists—about two-thirds of the material well decomposed (muck) and less than one-third of the plant material identifiable (muck);
- Hemists—about one-half of the material is well decomposed and the other half contains identifiable plant material (mucky peat);
- Fibrists—about one-third of the material is well decomposed and greater than two-thirds of the plant material is identifiable (peat).
- A fourth suborder, Folists, is less wet than other Histosols. Folists commonly form in decomposing leaves and twigs that overlie rock or fragmented materials (gravel, stones, etc.).

Organic soils are distinguished from mineral soils by processes and conditions affecting the rate and duration of plant detrital accumulations. Long-term dominance by plants that produce abundant below surface biomass under quiescent, shallow water conditions favors the formation of organic soils. Under this scenario, soils rapidly attain intense anaerobic conditions, with redox potential dropping to less than $-200\,\mathrm{mV}$ within a few days after flooding. Organic matter production rates far exceed the oxidation rates, resulting in organic matter accumulation, which can be substantial. For example, the sawgrass-derived organic deposits of south Florida have reached depths of several meters in some areas over about a 5000 year period.

Organic soils are far less extensive than mineral soils, but where they do occur they are commonly of considerable economic importance. Many have been artificially drained for agricultural purposes. Under drained conditions, aerobic biological oxidation of organic matter results in rapid rates of soil subsidence, with rates of about 2–3 cm year⁻¹ in the Everglades (Stephens, 1969; Snyder, 1987). The rate of soil subsidence can be reduced by implementing short-term (1–2 month) or long-term anaerobic conditions, such as through flooding or high water table management strategies.

20.3.4 Mineral Soils

Wetland soils that do not meet the taxonomic requirements for organic soils (e.g., Histosols) are mineral soils. The chemical reduction that accompanies saturated conditions generally results in features that are far more evident in mineral than organic soils, due to the masking effect (darkening) of organic matter for the latter. Reduction promotes dissolution of redox sensitive Fe and Mn oxides in soils, enabling their mobilization in accordance with principles of mass flow and diffusion until they encounter an oxidized zone where they reprecipitate as oxides. This redox-induced redistribution provides visual evidence of saturation and of redox gradients within the soil matrix, since both Fe and Mn are strong coloring agents (shades of yellow, brown, red, and black) in their oxide forms. Gray colored zones, in many cases, are attributable to reduction and depletion of these metals.

The process of gray color formation in mineral soils is sometimes referred to as "gleying" or "gleization." (Glossary of Soil Science Terms, 1997). Gray coloration corresponds to "low chroma" (<2) designations using the conventional Munsell notation for color characterization. A soil horizon dominated by redox-related gray colors is given the subordinate designation "g" (e.g., Btg). High chroma colors of various hues (e.g., browns or reds) in zones intermixed with gray colored zones are usually attributable to the oxidation, and subsequent concentration, of these metals. Over time, these zones of concentration may harden to form nodules and concretions. However, such hardened features, unless they have gradual or diffuse boundaries with the surrounding matrix, are indicative of relict rather than contemporary saturation. Features that reflect current wet–dry cycles tend to remain soft.

Historically, the patterns of gray in zones of periodic saturation were called "gray mottles." Gray coloration was used as a diagnostic criterion for saturation in both formal (e.g., in soil taxonomy) and informal (e.g., soil interpretations) contexts in soil science. However, soil scientists recognized that gray coloration is not always the result of chemical reduction. For example, gray colors are sometimes "inherited" from light colored parent material. Also, carbonates and clean sand grains tend to impart gray colors to soils. Hence, a new terminology was sought that would more explicitly and precisely convey the interpretations of saturation and reduction. Such a terminology was developed by the Committee on Soils with Aquic Moisture Regimes (Bouma, 1991). Interpretive morphological terms recommended by the committee were formally adopted for use in a revision of USDA soil taxonomy (Soil Survey Staff, 1999). Collectively, they are referred to as redoximorphic features. Redoximorphic features are now identified in standard soil descriptions, and include the following (Vepraskas, 1992):

- Redox concentrations: Bodies interpreted as redox-related concentrations of Fe and Mn.
 - Nodules and concretions: Partially hardened bodies.
 Concretions have concentric layers in cross-section, while nodules have a uniform internal fabric.

- b. Masses: Soft bodies with reddish or brownish colors.
- c. Pore linings: Zones of Fe and/or Mn accumulation along pore surfaces, as inferred from coloration.
- Redox depletions: Bodies of low chroma (gray colors) corresponding to zones where (i) Fe and Mn oxides have been depleted through reduction, and in some cases, (ii) clay has been depleted by mobilization due to the loss of the oxide cements.
- Reduced matrices: Soil matrices where low chroma is the result of chemical reduction of Fe, but not total depletion of Fe. A color change resulting from Fe oxidation occurs within 30 min.

Mineral soils, like organic soils, can have thick, dark surface horizons attributable to organic matter accumulation. These horizons may consist entirely of mineral soil material (i.e., below the organic C requirement for organic soil material). For example, many soils of semiarid prairie regions (e.g., Mollisols, USDA taxonomic system) have such surface horizons (called Mollic Epipedons) that are attributable to the climax grass vegetation rather than wetness per se. Alternatively, mineral soils can have organic soil material thick enough to qualify as Histic Epipedons. The distinction between the Mollic Epipedon and a Histic Epipedon, both dark and thick, can be important in wetland delineation (see Section 20.3.5) because the former is not necessarily a wetland indicator while the latter is a very reliable one. However, dark mineral surface horizons can be indicators of wetness in conjunction with immediately underlying redoximorphic features. In humid climates, for instance, surface horizons tend to be thicker and darker in wetlands.

20.3.5 Soils and Wetland Delineation: Hydric Soils Concept

Increased awareness of the important ecological role of wetlands has stimulated policies promoting wetland preservation. It has hence become necessary to delineate wetlands from uplands in a consistent and scientifically sound fashion for jurisdictional purposes. Soils are one of the three key components conventionally used to establish wetland boundaries, the others being vegetation and hydrology (Cowardin et al., 1979). Each component is ideally assessed independently. The soil assessment is particularly critical because soils are the most stable of the three components; for example, vegetation can be quickly altered and hydrology is sensitive to seasonal climatic fluctuations. The influences of prolonged saturation on soil properties, as previously discussed, are the crux of wetland soil delineation. Recent efforts have been made to document and catalog soil properties that are most consistently associated with wetland vegetation and hydrology.

"Wetland soils" could simply be defined as soils that occur in wetlands. However, this would be a circular definition if we intend to use soil characteristics as independent criteria in jurisdictional wetland delineation. Delineating wetland soil boundaries requires the specification of soil criteria that document the types of saturated conditions associated with wetland ecosystems. The term "hydric soils" is commonly used in jurisdictional language to apply to soils that meet such criteria. The USDA-Natural Resources Conservation Service (NRCS), in conjunction with the National Technical Committee for Hydric Soils, has defined hydric soils as "...soils formed under conditions of saturation, flooding, or ponding long enough during the growing season to develop anaerobic conditions in the upper part" (Federal Register, July 13, 1994). The growing season is the period of the year when soil temperature and moisture are most favorable for microbial activity, and hence anaerobiosis if the soil is saturated. Hydric soils, as defined, would tend to be wet even during the season when evapotranspiration loss is at a maximum.

The USDA hydric soils definition serves as a guideline for local technical limits used in jurisdictional wetlands delineation. However, the practical delineation of hydric soils generally requires some indirect assessment and professional judgment based on readily observable indicators associated with near surface saturation. Field indicators of hydric soils have evolved through collective observations and consensus, and have been formally cataloged by the USDA-NRCS (USDA-NRCS, 2006).

The USDA hydric soil indicators are specified as applying to (i) all soils, (ii) sandy soils, and (iii) loamy and clayey soils. Some are applicable to all USDA Land Resource Regions (USDA, 1981), while others are restricted to certain regions. Most of the indicators reflect pronounced organic matter accumulation at the surface, immediately underlain by redoximorphic features or other local subsurface features consistently indicative of saturation and anaerobiosis.

Delineation of hydric soils requires intensive soil investigation at wetland boundaries, since the interior areas are commonly wet enough that the hydric status is indisputable (i.e., the soils in the wettest areas have almost certainly developed "... anaerobic conditions in the upper part"). The uncertainty of hydric soil identification generally increases with proximity to the upland boundary, increasing the challenge of consistent delineation. The indicators that discriminate most effectively at the boundary are, therefore, the most useful. Soils examination generally requires only a shallow excavation (e.g., about 50 cm) using a tiling spade, since evidence for near surface saturation is being sought.

Detailed interpretive "hydric soils criteria" have been developed by USDA-NRCS (Federal Register, February 24, 1995) for the purpose of identifying soil series that could potentially be hydric soils. Series meeting the criteria are placed on a National Hydric Soils List (USDA, 1991). These hydric soils criteria encompass taxonomic and interpretive criteria linked with individual soil series within the USDA-NRCS soils data base. The criteria are not used in field delineation of hydric soils. The occurrence of a soil series on the USDA Hydric Soils List means only that a soil fitting the series in the field is potentially hydric. In effect, hydric and nonhydric soils could both fit the same series, since hydric soil status per se is not a series criterion.

20.4 Redox Gradients

In wetlands, O_2 is introduced into soils by diffusion through the floodwater, from photosynthetic O_2 production, by diffusion and mass flow from the atmosphere through plants into root zone, and by fluctuations in water table depth (Figure 20.3). Oxygen is crucial in regulating plant and microbial respiration rates, speciation, mobility, and bioavailability of chemicals in soils. However, when soils are flooded, O_2 exchange between the air–water–soil phases is severely curtailed, where O_2 diffusion through water is about 10^4 times slower than in air. Dissolved O_2 present in the soil porewater is rapidly consumed during aerobic respiration and approaches zero within a few hours depending on soil O_2 demand. Although not related to saturated soil conditions, application of O_2 -demanding wastes (animal wastes, composts, sewage sludge) or ammoniacal fertilizer can also result in O_2 depletion in the soil.

When O₂ is limiting, there is a shift in a number of properties that differentiate wetland and upland soils. Typically, there is an accumulation of organic matter, which may reach several meters of peat in some Histosols. Aerobic microbial activity that uses O₂ as the primary electron acceptor during catabolic activities is replaced by predominantly anaerobic activity, which obtains energy by oxidizing organic and inorganic compounds through several intermediate steps. The electrons released from these compounds pass through an electron transport chain containing several electron carriers that transfer electrons from energy substrates to terminal electron acceptors. In wetlands, O2 cannot always move into the soil rapidly enough to take care of the biological O2 demand of organisms because of pore blockage by water. Although O₂ supply to the soil is restricted as a result of flooding, its demand remains high. These conditions result in the development of two distinctly different soil layers: (1) an oxidized or aerobic surface soil layer containing O2, and (2) an underlying reduced anaerobic soil layer where no free O₂ is present (Figures 20.4 and 20.5). Diffusion of O2 through floodwater

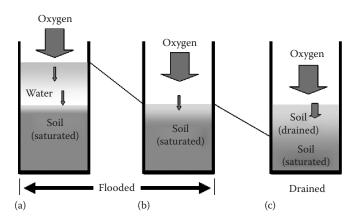

FIGURE 20.3 Patterns of oxygen penetration/movement into soils with varying degrees of saturation ranging from flooded (a) to surface saturated (b) to drained conditions (c). maintains the aerobic interface, which can vary in thickness from a few mm to 2–10 cm. In wetlands with dense layers of periphyton, production of $\rm O_2$ during photosynthesis may result in a thick aerobic zone during the day, while consumption of $\rm O_2$ during respiration may convert this layer to an anaerobic zone during the night. Thus, redox gradients at soil/floodwater interface can have diurnal fluctuations. The juxtaposition of aerobic and anaerobic soil layers and the temporal transitions of reducing and oxidizing conditions has major implications for the chemical and biological reactions in wetlands such as nitrification/denitrification, iron oxide-regulated precipitation of P, and oxidation of $\rm CH_4$, sulfides, and other reduced species.

The depth of the oxidized and anaerobic zones where a given electron acceptor is stable depends on the inflow of electron acceptors, the availability of organic and inorganic substrates, and hydrologic conditions. The sequential reduction of electron acceptors as a function depth follows the order of $\rm O_2$ reduction at the soil/floodwater interface, followed by other electron acceptors. The soil depths at which these reductions occur are depicted in Figure 20.6. It should be noted that different electron

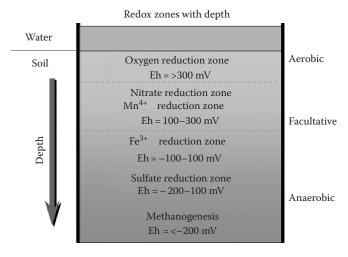

FIGURE 20.6 Typical depth distributions of microbial metabolic pathways in a vertical profile of a flooded soil or sediment.

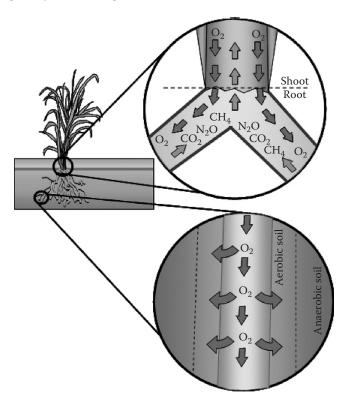

FIGURE 20.7 Schematic view of gas flow pathways in the stems and roots of plants adapted to wetland soil conditions. (From Reddy, K.R., and R.D. DeLaune. 2008. Biogeochemistry of wetlands: Science and applications. CRC Press, Boca Raton, FL.)

acceptors are utilized in the soil simultaneously at different soil depths. Thus, wetlands can be characterized by measuring the concentration of reduced species (Mn(II), Fe(II), S²⁻) or oxidized species such as $(O_2, NO_3^-, and SO_4^{2-})$.

Wetland plants have unique morphological and physiological adaptations for growing in anaerobic soil conditions. One of these adaptations is the development of internal air spaces (aerenchyma) for transporting $\rm O_2$ into the root zone (Figure 20.7). Depending on plant species, air spaces can occupy up to 60% of the total tissue (Brix, 1996). Oxygen transport in wetland plants occurs through molecular diffusion as a result of partial pressure gradients established within the system. In addition, temperature- and humidity-induced pressurization can move gases through mass flow (Armstrong and Armstrong, 1990; Brix et al., 1992).

Rates of O_2 transport by *Phragmites* range from 0.02 to 12 g m⁻² day⁻¹ (Brix, 1996). Studies have demonstrated the importance of this O_2 release into the root zone for supporting a wide array of processes including heterotrophic respiration and nitrification (Reddy et al., 1989a, 1989b). The wide range of reported O_2 transport rates has been attributed to seasonality and use of different experimental techniques. Low temperatures in colder climates can decrease internal pressurization, thus decreasing overall O_2 transport into the root zone.

20.5 Carbon

When compared to upland systems, most wetland soils show an accumulation of organic matter, and therefore, wetlands function as global sinks for C. The C cycle for a typical wetland is shown in Figure 20.8. Accumulation of organic C in wetlands is primarily a result of the balance of two processes: C fixation through photosynthesis and C loss through decomposition. Some natural and constructed wetlands receive significant internal and external loadings of organic C, associated with surface water runoff, carbonaceous wastewater, and diurnal tidal events. Anthropogenic inputs of organic C, including oil spills in coastal wetlands, and toxic organics in agricultural and industrial runoff, have not been well quantified in wetlands. Except for indirect effects on primary production, these inputs probably play a relatively minor role in the overall C budget of most wetlands.

Rates of photosynthesis in wetlands are generally higher than other ecosystems. For example, Houghton and Skole (1990) estimated mean primary productivity of a wetland ecosystem was approximately 1300 g C m⁻² year⁻¹, which is higher than many terrestrial tropical and subtropical ecosystems. In contrast, rates of decomposition in wetlands are typically lower than other systems due to the presence of anaerobic conditions. This imbalance in inputs and losses results in the net accumulation of organic matter in most wetlands. Net accumulation of C in some peatland ecosystems was found to be in the range 11–105 g C m⁻² year⁻¹ (Schlesinger, 1997). Rates are highly variable between wetlands depending on types of soil and vegetation, hydrology, nutrient inputs, extent of disturbance, presence of toxic substances, solar radiation, length of growing season and other

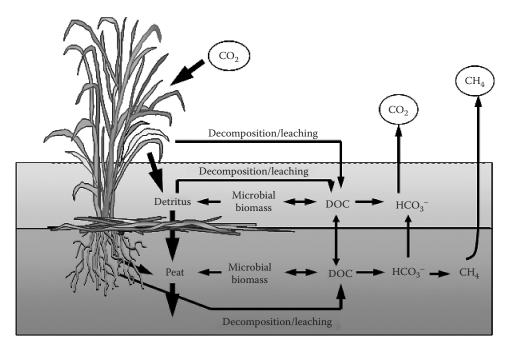

FIGURE 20.8 Schematic diagram of the general carbon cycle in wetlands. (From Reddy, K.R., and R.D. DeLaune. 2008. Biogeochemistry of wetlands: Science and applications. CRC Press, Boca Raton, FL.)

environmental factors. In addition to maintaining proper functioning of wetlands, organic matter storage also plays an important role in protecting other ecosystems and the biosphere. For example, because organic matter immobilizes nutrients such as N, P, and S, its accumulation in wetlands reduces eutrophication of downstream aquatic systems.

Organic C undergoes complex cycling in wetland systems and the fate of C depends on the specific type of molecule and environmental conditions. Easily degradable (labile) fractions are decomposed to inorganic constituents while recalcitrant pools are accreted as new peat layers. Organic matter associated with plant, algal, and microbial biomass in wetlands consists of complex mixtures of substances, including polymers (α -cellulose, hemicellulose, tannins, and lignins, proteins), water soluble monomers (amino acids, sugars, and nucleotide bases), and other extractable components (lipids, waxes, oils). Following frost or seasonal senescence, nonhumic substances are deposited in the water column and surface soil. Root exudates containing ethanol, carbohydrates, and amino acids may also contribute significant amounts of C to subsurface soils (Mendelssohn et al., 1981).

Labile organic C fractions undergo multistep conversions to inorganic constituents including (1) abiotic leaching of water soluble components and fragmentation of tissues into small pieces (<1 mm), (2) extracellular enzyme hydrolysis of biopolymers (nucleic acids, proteins, and carbohydrates) into monomers, and (3) aerobic and anaerobic catabolism of monomers by heterotrophic microorganisms (Figure 20.9). Abiotic leaching of algal and plant biomass is largely complete within days to months after deposition into water, but depends on amount of particulate and types of structural compounds. For example,

Gaur et al. (1992) measured leaching losses of up to 33% of water hyacinth mass after 4 days immersion in water column, while Benner et al. (1985) measured only 10%–20% losses of lignocellulosic components of plants in 1 month. Particulate materials remaining after initial leaching are typically fragmented by meiofauna before undergoing further decomposition. This step is critical because surface area is increased, allowing organisms and enzymes to penetrate tissues. Enzyme hydrolysis is generally considered the rate-limiting step in organic matter decomposition (Sinsabaugh, 1994).

The litter layer is a major support structure being a source of energy and nutrients and containing high numbers (109-1010 g-1 dry matter) of bacteria and fungi (Kjoller et al., 1985). Microbial biomass accounts for a significant amount of C in wetland substrates (DeBusk, 1996), and nutrients released from organic matter decomposition are available for plant uptake and growth. Enzymes such as cellulases and proteases excreted by fungi and bacteria hydrolyze large molecular weight biopolymers into oligomers and monomers that can be assimilated by microorganisms (Figure 20.9). The lack of available O2 in wetland soils further limits the activity of oxidoreductase enzymes such as peroxidases and phenoloxidases involved in lignin oxidation. For this reason, lignin degradation is most prevalent in aerobic zones such as soil-water and root-soil interfaces. Major fungal genera involved in decomposition in wetland systems include Alternaria, Cylindrocarpon, Cladosporium, Penicillium, Fusarium, Trichoderma, Alatospora, Tetracladium, Helicodendronm, and Helicoon (Kausik and Hynes, 1971; Given and Dickenson, 1975; Kjoller and Struwe, 1980). Most fungi are aerobes; therefore, bacteria generally dominate decomposition under anaerobic conditions (Alexander, 1977). Important bacterial genera involved in

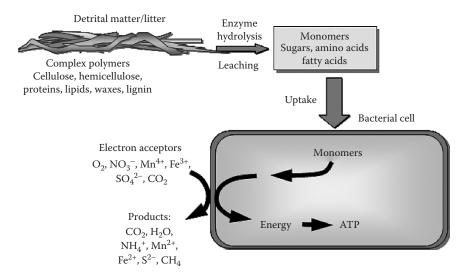

FIGURE 20.9 Diagram illustrating the flow of carbon from organic matter and the conversion of electron acceptors through microbial metabolism. (Adapted From Reddy, K.R., and R.D. DeLaune. 2008. Biogeochemistry of wetlands: Science and applications. CRC Press, Boca Raton, FL.)

extracellular enzyme hydrolysis of organic matter in wetlands include Cytophaga, Vibrio, Achromobacter, Bacillus, Micrococcus, Chromobacterium, Streptomyces, Arthrobacter, Actinomyces, Clostridia, Pseudomonas, Flavobacterium, Bacteriodes, Eubacterium, and Peptostreptococcus (Given and Dickenson, 1975; Molongoski and Klug, 1976; Wheatly et al., 1976).

Production and activity of extracellular enzymes are affected by a number of environmental factors including nutrients, pH, O₂ supply, humic and mineral substances, and inorganic cations. For example, Sinsabaugh et al. (1993) found that production of proteases and phosphatases was enhanced in N- and P-limited wetland systems, while lignocellulase activity and organic C mineralization were promoted under nonlimiting nutrient conditions. Fog (1988) concluded from a study of >60 sites that cellulose degradation was enhanced and lignin degradation was inhibited by inorganic and organic N amendments, probably resulting from N repression of phenoloxidase synthesis. Gordon and Millero (1985) demonstrated that biodegradation rates of low molecular weight organic acids and sugars were decreased due to sorption onto hydroxyapatite mineral surfaces. Goodwin and Zeikus (1987) found that anaerobic decomposition processes in acidic (pH 20.9) bog sediments are decreased, but that C and electron flow pathways are similar to those in neutral sediments. Kim and Wetzel (1993) demonstrated that humic substances complexed and curtailed the activity of extracellular enzymes, which was relieved by the presence of divalent cations such as Ca²⁺ and Mg²⁺. They speculated that this phenomenon may explain reduced decomposition in soft compared to hard water aquatic systems.

After enzyme hydrolysis, small molecular weight compounds are taken up and utilized as C and energy sources by heterotrophic microorganisms. A multitude of different microorganisms may be involved in this terminal step of decomposition, which depends largely on availability of electron acceptors (Figure 20.10). Diverse types of microorganisms couple oxidation of

organic C substrates (electron donors) with the reduction of electron acceptors to generate energy (ATP) required for growth. The most common electron acceptors include O_2 , NO_3^- , Mn(IV), Fe(III), SO₄²⁻, and CO₂, which enter wetlands through both internal and external inputs. For example, internal inputs include oxidation of chemical species (NH₄+, H₂S, Fe(II), and Mn(II)) that diffuse from anaerobic to aerobic soil zones. External inputs of electron acceptors include atmospheric O₂, seawater (SO₄²⁻), surface water runoff (NO₃⁻), and atmospheric deposition. Most wetlands contain several electron acceptors, so competition exists for electron donors between microbial groups. Due to differences in thermodynamic energy yield, electron acceptors are utilized to oxidize organic compounds in the order $O_2 > NO_3^- >$ $Mn(IV) > Fe(III) > SO_4^{2-} > CO_2$. Organisms that derive the most energy and have the fastest degradation kinetics outcompete other groups. This thermodynamic basis of bacterial competition explains both the temporal pattern after flooding and the vertical stratification of microbial activity and chemicals often observed in wetland soil profiles (Figure 20.11).

For these reasons, aerobic bacteria outcompete anaerobes. For example, DeBusk (1996) and D'Angelo and Reddy (1999) determined that aerobic C mineralization was about three times faster than under anaerobic conditions. Because recently deposited plant and algal detritus occurs typically in the water column and at the soil surface, most (70%-80%) decomposition occurs by aerobic fungi and bacteria (Kjoller and Struwe, 1980). Small zones at the root surface may also promote aerobic microbial activity (Schipper and Reddy, 1996). In contrast, root material and aboveground plant and algal biomass that are buried undergo anaerobic decomposition where microorganisms must utilize alternate electron acceptors to oxidize organic matter. The slower rates of these decomposition processes partially explain why wetlands accumulate organic matter more than upland systems. When wetland soils are drained, however, rapid rates of aerobic decomposition result in soil subsidence (e.g., 2-3 cm year⁻¹

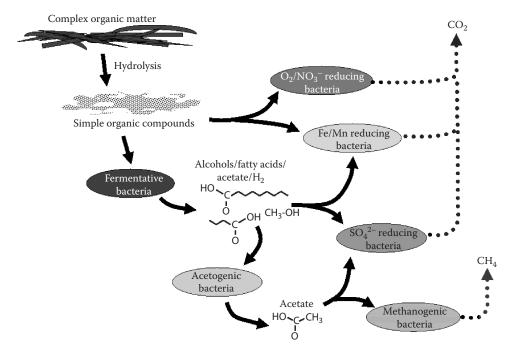

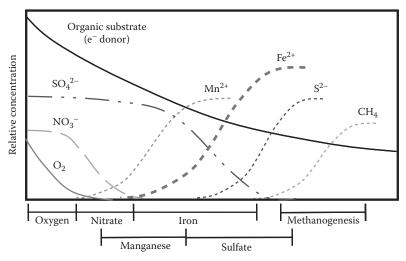

FIGURE 20.10 Idealized diagram showing the linkages between various microbial groups in the breakdown of organic matter to form the end products of respiration and methanogenesis.

Time after flooding or soil depth

FIGURE 20.11 Hypothetical pattern in concentrations of various oxidized and reduced chemical species following flooding of a soil or with depth into a flooded soil/sediment profile. in the Florida Everglades) (Snyder, 1987). Under such drained conditions, wetlands act as a source of C to the rest of the biosphere.

Carbon compounds that are recalcitrant to aerobic and anaerobic decomposition tend to accumulate in wetlands either as undecomposed plant tissues (peat) or humic substances (Figure 20.12). Formation of humic substances catalyzed by phenoloxidase enzymes in soils is thought to involve condensation reactions between reactive phenolic groups of tannins and lignins with water soluble nonhumic substances (Francois, 1990).

In the absence of O_2 , humic substances are resistant to decomposition, and so represent a significant C and nutrient storage in wetlands. Under drained conditions, humic substances are rapidly degraded, which releases nutrients to the bioavailable pool, thereby affecting downstream water quality. This humification process also accounts for the formation of large molecular weight and heterogenous humic substances that contain significant amounts of N, P, S in their structures. For example, P contained in humic substances may make up between 40% and 90% of the total P in Histosols (DeBusk et al., 1994).

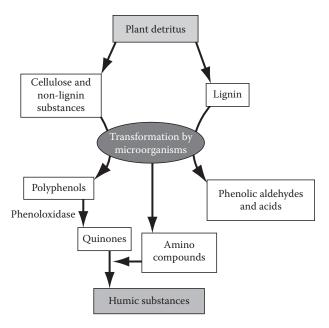

FIGURE 20.12 Diagram of hypothesized reactions and processes resulting in the formation of humic substances from plant detritus. (From Reddy, K.R., and R.D. DeLaune. 2008. Biogeochemistry of wetlands: Science and applications. CRC Press, Boca Raton, FL.)

20.6 Nitrogen

Nitrogen is a major nutrient in wetlands and often controls primary productivity, especially under conditions of excessive P supply. Nitrogen is present in aquatic systems in organic forms and as inorganic forms such as dinitrogen gas (N₂), nitrate (NO₃⁻), nitrite (NO₂⁻), ammonium (NH₄⁺), and trace gases such as N₂O. Organic N is derived primarily from amino-bonded C (–NH₂) such as amino acids and proteins, and nucleic acids and amino sugars. Generally, the sum of NO₃⁻/NO₂⁻, and NH₄⁺ measured after filtration is taken to represent dissolved inorganic N (DIN). The difference between the total dissolved N of

a system and its DIN is then defined as the dissolved organic N (DON). Particulate forms are removed through settling and burial, while the removal of dissolved forms is regulated by various biogeochemical reactions functioning in soil and water column (Figure 20.13). Traditionally, only NO₃⁻ and NH₄⁺ have been considered biologically available; however, it has also been noted that organic forms of N, such as amino acids and other small molecular weight N compounds (e.g., urea) can be a significant source of N to both microbial/algal communities (e.g., Berman and Bronk, 2003; Linares and Sundback, 2006) and wetland macrophytes (e.g., Nasholm et al., 2009). This is important not only because of its role in nutrition in N limited systems, but also because the presence of organic forms of N (in particular, urea) has been shown to affect algal species composition (e.g., Heil et al., 2007).

Nitrogen is also present at various valence states ranging from -3 (NH₃) to +5 (NO₃⁻). The wide range in oxidation numbers provides the possibility for several oxidation-reduction reactions. Relative rates of these reactions are affected by physicochemical and biological characteristics of soils, organic substrates, and the water column. Detailed reviews of N processes functioning in the soil and the overlying water column of wetlands were presented by Reddy and Patrick (1984), Bowden (1987), Johnston (1991), Howard-Williams and Downes (1993), and Reddy and D'Angelo (1994). Several N transformations effectively process inorganic N through nitrification and denitrification, ammonia volatilization, and plant and microbial uptake, and maintain relatively low levels of inorganic N in the water column. The extent of these processes usually increases with N loading.

Nitrogen can enter wetlands through a variety of pathways including atmospheric deposition, biological nitrogen fixation, or through surface- or groundwater inputs. Atmospheric deposition is highly variable and can contribute anywhere from $\sim 0.005\,\mathrm{g}$ N m⁻² year⁻¹ in remote areas to >2 g N m⁻² year⁻¹ in areas near urbanized centers (Galloway et al., 2004). By comparison, the process of biological nitrogen fixation, which converts atmospheric N₂ gas into biologically available NH₄-N, can

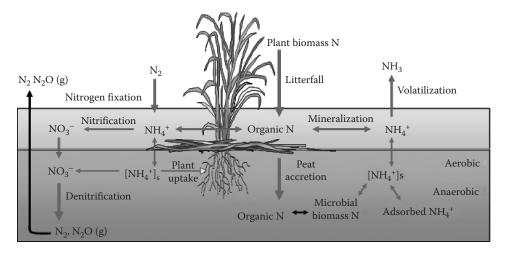

FIGURE 20.13 Schematic diagram of the general nitrogen cycle in wetlands. (From Reddy, K.R., and R.D. DeLaune. 2008. Biogeochemistry of wetlands: Science and applications. CRC Press, Boca Raton, FL.)

add >37 g N m⁻² year⁻¹ to N-limited wetland systems (reviewed by Inglett et al., 2004). In particular, cyanobacterial mats have been shown to exhibit rates of N_2 fixation of >74 g N m⁻² year⁻¹ (Howarth et al., 1988). Such high rates of fixation help contribute to the high productivity of these mats and other conspicuous periphytic forms.

Plants derive most of their N from soil porewater with only a small amount of the floodwater N being directly utilized. The ratio of tissue N to tissue P (N:P ratio) can be an effective indicator of N demand/limitation by wetland vegetation (Koerselman and Mueleman, 1996). Efficiency of N utilization (defined as increase in plant N per unit mass of available N) by aquatic vegetation is highly variable, depending on the type of wetland vegetation (woody versus herbaceous), nutrient loading, and temperature. The N-use efficiency of aquatic vegetation and the C/N ratio of plant litter decrease with nutrient loading (Shaver and Melillo, 1984; Reddy and Portier, 1987; Koch and Reddy, 1992). Elevation of temperature from 10°C to 25°C was shown to increase N-use efficiency by *Typha* spp. from 5% to 38% (Reddy and Portier, 1987).

In temperate climates, most N assimilation occurs during the growing season. During winter months, aboveground biomass is killed and accumulates as detrital tissue. At the same time, a significant portion of N is translocated to below ground biomass. Nitrogen assimilation by herbaceous vegetation is usually short term and usually cycled rapidly within the systems. Unlike herbaceous macrophytes, forested wetlands provide long-term storage in the form of woody biomass. However, a significant portion of nutrients stored in the leaves are returned to the forest floor, and eventually incorporated into the soil (Reddy and DeBusk, 1987). Because forest litter decomposition is slow, turnover periods are much longer. Measurement of plant tissue N and biomass can provide an indication of N removal efficiency by wetlands.

Breakdown of detrital tissue results in release of DON to the water column, most of which is resistant to decomposition. Under these conditions, water leaving wetlands may contain elevated levels of N in organic forms. Wetlands usually function as effective sinks for inorganic N, and as sources for organic N. Net release of NH₄-N by wetland soils is determined by the balance between ammonification and immobilization, which is controlled by the N requirements of microorganisms involved, the nature of organic N forms, and other soil and environmental factors (Figure 20.14). Because of the low N requirements of anaerobic microorganisms, wetland soils usually accumulate NH₄-N, which supports most of the N requirements of wetland plants and microbes. Organic N mineralization can be described as a function of the detritus C/N ratio, activity of extracellular enzymes (e.g., protease), microbial biomass, and soil redox conditions (McLatchey and Reddy, 1998). Stanford et al. (1973) also demonstrated a temperature dependence of organic N mineralization (with Q₁₀ values of about 2 between 15°C and 35°C), and that the effect of temperature differed between plant types (greater effect for Sagittaria compared to Typha tissues). These results suggest that the variety of wetland types and conditions

may contribute to a great diversity of organic N mineralization rates and patterns in many systems.

Ammonium released during mineralization has a variety of fates in wetlands (Figure 20.15). The positive charge of the NH₄⁺ ion results in a significant attraction of this N species with soil particles (in particular, humic substances and clay minerals) having a net negative surface charge. This adsorption process can affect the availability and retention of nitrogen in systems and is comparatively different than that of NO₃⁻, which is not retained on soil/sediment particles. Free NH₄⁺ can also undergo a pH-controlled conversion to gaseous NH₃, which may rapidly be lost from the watercolumn via ammonia volatilization (Figure 20.16) [Reactions (20.9) and (20.10)].

$$NH_4^+ + OH^- \rightarrow NH_3(aq) + H_2O$$

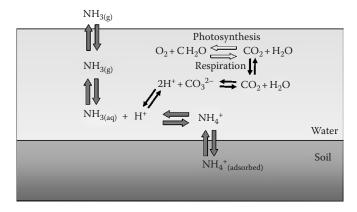

FIGURE 20.16 Schematic view of processes related to the flux of ammonium (NH_4^+) and the pH controlled processes relating to the process of ammonia volatilization. (From Reddy, K.R., and R.D. DeLaune. 2008. Biogeochemistry of wetlands: Science and applications. CRC Press, Boca Raton, FL.)

Ammonia volatilization is an abiotic reaction influenced by the physicochemical characteristics of a wetland water column. Ammonia volatilization is regulated by $\mathrm{NH_3}$ concentration, temperature, vegetation density, air movement above the water surface, mixing in the water column, algal activity, and associated pH fluctuations. In wetlands, this process can play a significant role if the influent water contains high levels of $\mathrm{NH_4}\text{-N}$, and photosynthetic activity by algae or submerged aquatic vegetation drives the pH above 8.5.

Ammonium oxidation (nitrification) is a two-step process mediated by aerobic chemoautotrophic bacteria, *Nitrosomonas* (NH_4^+ to NO_2^-) and *Nitrobacter* (NO_2^- to NO_3^-). These bacteria derive energy for biosynthesis from oxidation of NH_4^+ and NO_2^- , while using HCO_3^- as a C source.

$$NH_4^+ + 2O_2 \rightarrow NO_2^- \rightarrow NO_3^- + 2H^+ + H_2O$$
 (20.11)

Since nitrification is an aerobic process, it occurs in the water column, surface aerobic soil layer, and root zone. The relative importance of these zones in overall nitrification depends on $\rm O_2$ availability and NH₄-N concentration (Reddy and Patrick, 1984). Nitrification rates are reported to be in the range of 0.01–0.161 g N m $^{-1}$ day $^{-1}$ (mean = 0.048 \pm 0.044) (Martin and Reddy, 1997). These values are lower than those reported for mineralization, suggesting that $\rm O_2$ and NH₄-N availability limit nitrification. Nitrifiers compete with other heterotrophic and lithotrophic organisms for $\rm O_2$. In wetland environments, $\rm O_2$ is probably the primary regulator of nitrification.

Nitrate added to or produced in wetlands can be used during assimilatory or dissimilatory NO_3^- reduction. During assimilatory NO_3^- reduction, microorganisms and plants assimilate NO_3^- into their biomass after reduction to NH_4^+ and incorporation into monomers (amino acids) and biopolymers (proteins). Dissimilatory NO_3^- reduction is divided into two main pathways: denitrification (Reaction (20.12)) and dissimilatory NO_3^- reduction to ammonium (DNRA)(Reaction (20.13)). In both

cases, NO_3^- is used as an electron acceptor for energy generation by anaerobic bacteria.

$$5C_6H_{12}O_6 + 24NO_3^- + 24H^+ \rightarrow 30CO_2 + 12N_2 + 42H_2O$$
 (20.12)

$$C_6H_{12}O_6 + 3NO_3^- + 6H^+ \rightarrow 6CO_2 + 3NH_4^+ + 3H_2O$$
 (20.13)

Denitrification occurs at higher Eh levels (200-300 mV) than dissimilatory reduction (<0 mV). Denitrification is typically the dominant pathway of NO₃⁻ removal in wetlands. Reported NO_3 removal rates by wetlands are in the range of 0.003–1.02 g N m⁻² day⁻¹ (mean = 0.097 ± 0.139). In most wetlands, denitrification rates are usually limited by NO3- concentrations and diffusion rates of NO₃- from aerobic to anaerobic sites (Martin and Reddy, 1997). Denitrification rates are usually higher in soils receiving steady loadings of NO₃⁻ than soils receiving low or negligible levels (Cooper, 1990; Gale et al., 1993). In a system with active denitrification, NO₃- levels are usually maintained at low levels, thus measurement of NO₃⁻ in soil and water column may not provide reliable indication of this process. Since denitrification is mediated by heterotrophic microorganisms, its rate may also be regulated by available organic C (electron donor). Significant correlations have been observed between denitrification rates and available organic C (mineralizable organic C) (Burford and Bremner, 1975; Reddy et al., 1982; Gale et al., 1993).

The high energetic potential of using NO_3^- as an electron acceptor is not solely possessed by heterotrophic bacteria, and conversion of NO_3^- can also occur by additional pathways (reviewed by Burgin and Hamilton, 2007) (Figure 20.17). Many of these pathways have yet to be identified in wetlands; however, the potential still exists for these processes to account for significant reduction of NO_3^- in aquatic systems (e.g., systems with high levels of reduced Fe(II), S^0 , and S^{2-}) This finding has challenged the classical view of the sole importance of denitrification in aquatic systems. Among the possible pathways, NO_3^- reduction to N_2 can be coupled to the lithotrophic oxidation of either reduced

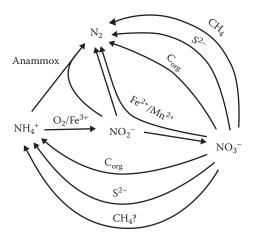

FIGURE 20.17 Diagram depicting the potential pathways of nitrate reduction in aquatic systems.

iron (Fe(II)) or sulfur (S 0 , S $^{2-}$), or even methane. Alternatively, NO $_{3}^{-}$ reduction via S $^{2-}$ oxidation can occur through lithotrophic DNRA where the product NH $_{4}^{+}$ is not directly incorporated into biomass. Strongly reducing conditions with high contents of organic matter or high concentrations of reduced Fe and S are required for DNRA. As for lithotrophic denitrification, conditions may also exist for lithotrophic DNRA activity in wetlands with accumulations of reduced iron and sulfur.

Most recently, a novel pathway for N conversion to N, has been identified, which adds even more uncertainty to the aquatic N cycle. The process known as anaerobic ammonium oxidation (Anammox) has now been identified in a number of freshwater systems including lakes and wetlands. This process occurs in strictly anaerobic conditions, and couples the reduction of NO2- with the oxidation of NH4+ to produce N2 gas. Anammox bacteria appear to be autotrophic, and the presence of organic matter slows the Anammox process. Another important requirement for the Anammox process is the presence of NO₂-, which is rarely observed in most wetland systems. Nitrite accumulation is possible however, such as in cases of incomplete denitrification (e.g., lack of suitable organic substrates or high concentrations of NO₃-) (Herbert, 1982; Smith et al., 1997) or partial ammonium oxidation (low O2 availability or inhibition by ammonia) (Anthonsieu et al., 1976; Smith et al., 1997). Likewise, NO₂- accumulation is a common trait of DNRA (Cole, 1988) resulting from either inhibitory effects of NO₃⁻ on NO₂⁻ reductase (Smith, 1982) or repression of this enzyme (Paul and Beauchamp, 1989). Higher than expected NO₂-levels (100–200 μg N L⁻¹) have been reported in some rivers, particularly in watersheds receiving large inputs of nitrogenous pollution, and the NO₂- accumulation corresponded with areas of high DNRA activity (Smith et al., 1995; Kelso et al., 1997). All of these studies suggest NO2- may be much more abundant than previously thought, and it is possible that NO2- levels may be sufficient to support alternative N cycling pathways in wetlands (such as Anammox).

Whether a wetland acts as a sink or source of N depends on the net effects of the input and loss processes described here. Several studies have used mass balance methods to estimate N retention within a wetland (DeLaune et al., 1989; White and Howes, 1994). These studies showed that N demand of aquatic vegetation, microbial, and periphyton communities is not met by external inputs alone, pointing to the role of internal cycling and turnover. Based on the pathways of N cycling, vegetation can play a significant role in the wetland N cycle by: (1) assimilating N into plant tissue, (2) releasing N through tissue mineralization, and (3) providing an environment in the root zone for nitrification-denitrification to occur. A few studies have quantified the role of remineralization of organic N during plant litter decomposition and belowground biomass turnover. Values of 54%-95% of plant uptake demand being met through this process have been reported (Hopkinson and Schubauer, 1984; DeLaune et al., 1989; White and Howes, 1994). In a greenhouse study, fertilizer inorganic N was the major source during the early part of the cattail growing season, while soil organic N mineralization supplied plant N requirements during the latter part of the growing season (Reddy and Portier, 1987).

The predominance of organic matter accumulation results in the dominant mechanism of N retention in wetlands being through organic N accumulation. Inputs of NO₃⁻ and NH₄⁺ are rapidly taken up or lost via nitrification–denitrification processes. Nitrogen availability to vegetation is thus frequently controlled by the rate of organic N mineralization, and the relative magnitude of N loss mechanisms such as denitrification and NH₃ volatilization. The limiting processes regulating N loss from wetlands by these mechanisms are NH₄⁺ diffusion from anaerobic to aerobic zones and nitrification in aerobic zones. Denitrification is limited by NO₃⁻ availability, since most wetlands have abundant supplies of energy. Nitrification–denitrification pathways are key processes that return N to the atmosphere and complete the N cycle.

20.7 Phosphorus

Unlike C and N, P tends to accumulate in wetlands because there is no significant gaseous loss mechanism. Phosphorus retention by wetlands is regulated by physical (sedimentation and entrainment) and biological mechanisms (uptake and release by vegetation, periphyton and microorganisms) (Figure 20.18). Several reviews have discussed the mechanisms of P retention and cycling in stream and lake sediments, uplands, and wetlands (Khalid et al., 1977; Berkheiser et al., 1980; Bostrom et al., 1982; Logan, 1982; Sonzogni et al., 1982; Howard-Williams, 1985; Froelich, 1988; Reddy and D'Angelo, 1994; Reddy et al., 1999).

Phosphorus entering a wetland system is typically present in both organic and inorganic forms. The relative proportion of each form depends upon the geology, soil, vegetation, and land use characteristics of the watershed. For example, municipal wastewater may contain a large proportion (>75%) as inorganic P in soluble forms, as compared to effluents from agricultural watersheds. To trace the transport and transformations of P, it is convenient to classify forms of P entering these systems as (1) dissolved inorganic P (DIP), (2) dissolved organic P (DOP), (3) particulate inorganic P (PIP), and (4) particulate organic P (POP) (Figure 20.18). The particulate and soluble organic fractions may be further separated into labile and refractory components. DIP is considered bioavailable, whereas organic and particulate P forms generally must undergo transformations to inorganic forms before being considered bioavailable (Figure 20.19).

Phosphorus present in wetland soils can be grouped into: (1) orthophosphate ions sorbed onto the surface of P-retaining components (non-occluded P), (2) P absorbed within the matrices of P-retaining components (occluded P), and (3) phosphate minerals such as apatite or strengite (Williams et al., 1971). These P forms are characterized based on their differential solubilities in various chemical extractants. Several chemical fractionation schemes have been used to identify discrete pools of inorganic P, including exchangeable, Fe/Al bound, and Ca/Mg bound P (Hieltjes and Lijklema, 1980; Olila et al., 1994; Reddy et al., 1995).

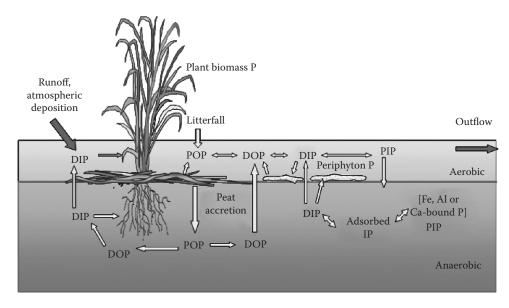

FIGURE 20.18 (See color insert.) Schematic diagram of the general phosphorus cycle in wetlands. (From Reddy, K.R., and R.D. DeLaune. 2008. Biogeochemistry of wetlands: Science and applications. CRC Press, Boca Raton, FL.) POP-Particulate organic P, PIP-particulate inorganic P, DOP-dissolved organic P, DIP-dissolved inorganic P, IP-inorganic P.

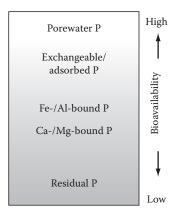

FIGURE 20.19 Schematic showing the relative bioavailability of various P forms in wetland soils. (From Reddy, K.R., and R.D. DeLaune. 2008. Biogeochemistry of wetlands: Science and applications. CRC Press, Boca Raton, FL.)

The example in Figure 20.20 shows labile and nonlabile pools of P in selected stream sediments of south Florida (Reddy et al., 1995). In this example, the inorganic P extracted with neutral salt such as KCl represents loosely absorbed P, which usually accounts for less than 2% of the total P (Figure 20.20). This pool of P is considered bioavailable as it is sufficiently labile to enter porewater for uptake of plants or potential flux into the overlying water column. The NaOH-P_i represents inorganic P associated with Fe and Al, and represents P not readily available. The HCl-P_i represents P associated with Ca/Mg, is also relatively stable and not readily available. Alkali extractable organic P includes both readily available organic P (microbial biomass P) and slowly available organic P (P associated with fulvic and humic acids). Residual P represents highly resistant organic P or unavailable mineral bound P not extracted either with

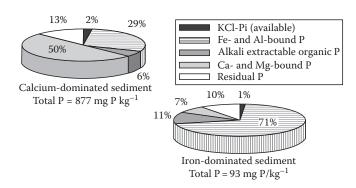

FIGURE 20.20 Comparison of phosphorus distribution in two wetlands on the basis of pools defined by various chemical extractants. (Adapted From Reddy, K.R., and R.D. DeLaune. 2008. Biogeochemistry of wetlands: Science and applications. CRC Press, Boca Raton, FL.)

alkali or acid. The Ca-bound P such as apatite has been found to be unavailable (Pettersson, 1986; Gunatilaka, 1988), while the redox-sensitive Fe-bound P may become available under anaerobic conditions (Wildung et al., 1977; Hosomi et al., 1981; Furumai and Ohgaki, 1982).

The organic P fraction in soils and sediments accounts for a high proportion of total P: 20%–60% in mineral soils (Tiessen et al., 1994), 10%–70% in lake sediments, and 40%–90% in Histosols (DeBusk et al., 1994). Most of the organic P in soils is derived from plant detritus and in part synthesized by soil organisms from inorganic sources (Sanyal and DeDatta, 1991). Organic P associated with humic and fulvic acids represents greater than 40% of total soil P (Brannon and Sommers, 1985). The fulvic acid P constitutes a large fraction of the organic P in most soils and it is likely that this pool is derived from plant litter and recently deposited organic matter (Stewart and Tiessen, 1987).

Organic P in biological tissues and cells can be classified into three groups: (1) inositol phosphates, (2) nucleic acids, and (3) phospholipids (Anderson, 1980), with inositol phosphates comprising up to 60% of the soil organic P (Tate, 1984). Phosphorus is bound in most organic compounds as an ester (C-O-P) (Cosgrove, 1977; Golterman, 1984), a form not readily bioavailable until it undergoes enzyme hydrolysis (Harrison, 1983; Hoppe et al., 1988; Chrost, 1991). Extracellular enzyme activity (such as alkaline and acid phosphatases), which hydrolyzes P esters, increases under inorganic P-limiting conditions (McGill and Cole, 1981). In contrast, phosphatase activity is usually lower in areas of high P availability (such as wetlands receiving P inputs); however, eutrophic systems also exhibit high P mineralization rate primarily due to enhanced substrate biodegradability (Newman and Reddy, 1993).

Phosphorus uptake by vegetation is much like that of N, being maximal during the peak growing season, followed by a decrease or cessation in the fall and winter. During winter periods, a significant portion of the P is translocated to belowground biomass (roots and rhizomes) (Davis and van der Valk, 1983). Phosphorus storage in the aboveground biomass of macrophytes is usually short term, with large amounts of P being released during decomposition of detrital tissue. Phosphorus release rates during summer are four to sixfold faster than in winter months. Emergent macrophytes, which have an extensive network of roots, and rhizomes responsible for uptake and storage of P can assimilate little P directly from floodwater (Richardson and Marshall, 1986). Davis (1982) measured only 2%-4% of added floodwater ³²P in the living tissue of *Cladium* and *Typha*, however, the active uptake of soil porewater P by these plants can potentially increase the flux of P from the water column into the soil, thus improving overall P retention.

Phosphorus is cycled in soil-water-plant compartments as follows. Herbaceous vegetation rooted in soils obtains most of its P requirements from the soil porewater and translocates it to aboveground vegetation. Upon maturity and senescence, a substantial portion of the P present in the aboveground vegetation can be translocated and stored in belowground biomass (roots and rhizomes). Estimates are that about 45% of the P lost from living Typha spp. shoots was translocated to roots and rhizomes (Davis and van der Valk, 1983). Depending on the type of aquatic macrophyte, up to 80% of the remaining P stored in the aboveground detrital tissue in nutrient-rich systems is released into the water column either by initial leaching or as a result of decomposition. The detrital tissue deposited on the soil surface is subjected to decomposition, with residual detrital material becoming an integral part of the soil and providing long-term storage (Caraco et al., 1991; Gachter and Meyer, 1993; D'Angelo and Reddy, 1994a, 1994b; Koch et al., 1994). Over the short term, however, rapid turnover rates and cycling can contribute bioavailable P to the water column and influence water quality.

Apart from plant uptake, inorganic P in the porewater interacts with the soil solid phases through a series of adsorption/desorption processes (Figure 20.21). During these reactions, the ${\rm PO_4}^{\rm 3-}$ ion is held by various positively and neutrally charged sites on

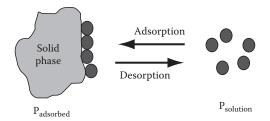

FIGURE 20.21 Schematic representing the process of phosphorus association with the soil solid phase through adsorption/desorption. (From Reddy, K.R., and R.D. DeLaune. 2008. Biogeochemistry of wetlands: Science and applications. CRC Press, Boca Raton, FL.)

soil particles such as sites of permanent charge in clay minerals, pH dependent sites on minerals and organic matter, or through ligand exchange with hydroxyl functional groups of iron and aluminum hydroxides and oxyhydroxides. Precipitation reactions (with calcium, magnesium, iron and aluminum) can also complex P within the soil matrix. The net effect of adsorption/desorption depends on the types of minerals, redox status, pH, organic matter content of each soil/sediment type, and the relative amount of P already stored on these sites. In this manner, adsorption/ desorption processes regulate a complex equilibrium between the P in the soil solid and solution phases. The equilibrium P concentration (EPC₀) is often a useful parameter to characterize the P adsorption/desorption behavior of different soils or sediments. The EPC₀ is generally derived using a P isotherm to represent the amount of P lost or retained on the soil solid phase at various P concentrations (Figure 20.22). From this mathematical representation, soils with a higher potential to release P into solution have comparatively higher EPC₀ than soils or sediments that have lower EPC₀ values (Figure 20.23).

Inorganic P added to wetlands at concentrations considerably greater than those present in the soil porewater diffuses to the soil and is retained by oxides and hydroxides of Fe and Al in acid soils and by CaCO₃ in alkaline soils. In soils dominated by Fe oxides, P can be readily immobilized through sorption by ferric oxyhydroxide and precipitation as ferric phosphate in the

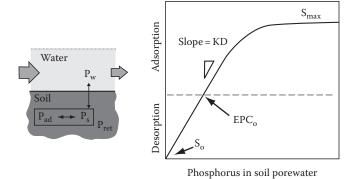

FIGURE 20.22 Illustration of the concept of phosphorus isotherms and the derivation of parameters to characterize phosphorus adsorption and desorption in soils or sediments. FIGURE 20.23 Comparison of typical isotherms from soils with high and low loading of phosphorus. (From Reddy, K.R., and R.D. DeLaune. 2008. Biogeochemistry of wetlands: Science and applications. CRC Press, Boca Raton, FL.)

oxidized zones at the soil–water interface. The rate of adsorption is controlled by soil pH and Eh, adsorptive surface area (active Fe and Al or CaCO₃), and temperature. In calcareous systems, P can be precipitated as Ca mineral bound P, especially when the pH of the floodwater is increased by algal photosynthetic activity (pH as high as 10). At night, respiration by algae and bacteria can result in a resolubilization of Ca-precipitated P (Figure 20.24) (Diaz et al., 1994). In calcareous systems, coprecipitation of P with CaCO₃ is believed to be a dominant mechanism in the immobilization of soluble P.

The retention of P in noncalcareous systems can be represented by the following empirical relationship that was derived for a number of wetland mineral soils and stream sediments in Florida (Reddy et al., 1998):

$$S_{max} = 0.24 [oxalate Fe + Al]$$
 (20.14)

where

 S_{max} is maximum P retention capacity [oxalate Fe + Al] is ammonium oxalate extractable Fe and Al

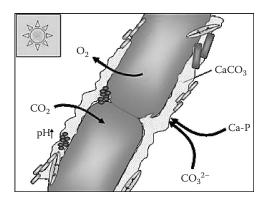

The above equation is applicable for [Fe + Al] concentration in the range of 0–100 mmol kg⁻¹. According to this relationship, about 4 mol of Fe + Al are needed to retain 1 mol of P. Other researchers have reported a significant relationship between extractable Fe and Al, and the P-retention capacity of wetland soils (Richardson, 1985; Walbridge and Struthers, 1993; Gale et al., 1994; Lookman et al., 1995; D'Angelo, 2005). These relationships suggest that extractable Fe and Al can be used as a predictor of P retention by wetland mineral soils. In sulfate-dominated wetlands, production of sulfides and removal of Fe(II) through precipitation as ferrous sulfide may preclude P retention by Fe(II) compounds (Caraco et al., 1991).

20.8 Metals

Alterations in Eh and pH in wetland soils affect the reactivity and mobility of metals. Many oxidized stable metallic compounds are reduced into more soluble and bioavailable forms under wetland conditions. Although many metals are present in the wetland environment, two metallic cations (Fe and Mn) play a major role in most wetland mineral soils. Ferric iron (Fe(III)) and Mn(IV) reduction coupled with organic matter turnover is considered as one of the significant mechanisms in anaerobic habitats (Lovley, 1991; Nealson and Myers, 1992). In wetland soil environments, Fe(III) and Mn(IV) reduction is mediated by enzymatic activity, which couples the use of these compounds as electron acceptors during microbial respiration. However, nonenzymatic reduction of Fe(III) and Mn(IV) has also been reported in anaerobic environments (Lovley et al., 1991). Both Fe and Mn are present as solid phases in oxidized form (such as Fe₂O₃, FeOOH, FePO₄, and MnO₂), which are reduced to more dissolved forms under anaerobic conditions (Figures 20.25 and 20.26). Typical Fe(III) reduction under wetland soils conditions and its relationship to Eh and pe is shown below:

$$Fe(OH)_3 + 3H^+ + e^- \rightarrow Fe^{2+} + 3H_2O$$
 (20.15)

Eh =
$$1.06 - 0.059 \log Fe^{2+} - 0.177 \text{ pH}$$
 (20.16)

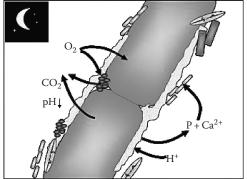

FIGURE 20.24 Depiction of diel processes affecting co-precipitation of phosphorus with calcium in algal dominated systems. (From Reddy, K.R., and R.D. DeLaune. 2008. Biogeochemistry of wetlands: Science and applications. CRC Press, Boca Raton, FL.)

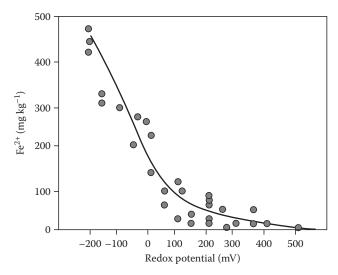

FIGURE 20.25 Influence of redox potential on reduction of oxidized Iron(III) to form Iron(II) (Fe²⁺). (From Reddy, K.R., and R.D. DeLaune. 2008. Biogeochemistry of wetlands: Science and applications. CRC Press, Boca Raton, FL.)

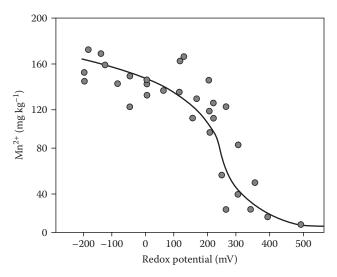

FIGURE 20.26 Influence of redox potential on reduction of oxidized Manganese(IV) to form Manganese(II) (Mn²⁺). (From Reddy, K.R., and R.D. DeLaune. 2008. Biogeochemistry of wetlands: Science and applications. CRC Press, Boca Raton, FL.)

$$pe = 17.87 + pFe^{2+} - 3 pH$$
 (20.17)

Reduction of metallic compounds is inhibited by the presence of O₂ and to some extent by NO₃-. The reduction of Fe(III) and Mn(IV) has direct impacts on soil chemistry, such as (1) increased water soluble Fe(II) and Mn(II), (2) increased pH, (3) displacement of other cations from the soil exchange complex into porewater, (4) breakdown of organic matter and nutrient release, (5) increased solubility of P and Si, and (6) formation of new minerals (Ponnamperuma, 1972; Gambrell, 1994).

Reduction of Fe(III) and Mn(IV) depends on the supply of electron donors (primarily availability of labile organic matter), and the concentrations of bioavailable oxidized Fe and Mn. Microbial reduction also depends on the ability of bacteria to solubilize solid phases, attach directly to the substrate and transfer electrons, and/or transport the substrate directly into cells as a solid. Reduction capacity of the oxidized Fe compounds decreases with increasing crystallinity: $FePO_4 > Fe(OH)_3 > FeOOH > Fe_2O_3$ (Lovley, 1987). Iron forms more stable organic metal bonds than Mn, which protects it from precipitation reactions. The extent of complexation is greater under wetland soil conditions because of high concentrations of dissolved organic compounds in porewater. Significant amounts of Fe(II) can be present under aerobic conditions for several days due to complexation with organics.

General chemical forms of trace metals in wetland soil are (1) water soluble forms, such as free ions, inorganic and organic complexes, (2) exchangeable metals, (3) metals precipitated as inorganic compounds, (4) metals complexed with large molecular weight humic materials, (5) metals adsorbed or occluded in precipitated hydrous oxides, (6) metals precipitated as insoluble sulfides, and (7) metals bound within the crystalline lattice structure of primary minerals (Gambrell, 1994). These mechanisms often make wetland soils effective sinks for many trace metals (Gambrell, 1994).

One important location of metal binding in wetlands is the rhizosphere where O₂ leaking from roots precipitates Fe (as Fe oxides) in what is known as a root "plaque." Many other metals such as As, Zn, and Ni can also co-precipitate in these root plaques making them effective at metal removal in wastewaters and metal accumulation (e.g., Zn) in wetland plants (reviewed by Jacob and Otte, 2003). In anaerobic soil zones, high levels of S²⁻ result in the effective precipitation of many metals such as Zn, Pb, and Hg. This is particularly important in estuarine wetlands or coastal soils/sediments, but sulfur additions to freshwater systems can also result in the reduction of metal availability. One example is in the Florida Everglades where areas of highest sulfur additions (from agricultural drainages) exhibited the lowest levels of toxic Hg (as methyl-mercury) (Benoit et al., 1999; Krabbenhoft et al., 2000).

Processes which tend to bind metals under anaerobic conditions are not irreversible, however, and are subject to water table fluctuations or wetland drainage which can reverse many of these reactions. For example, in wetland mineral soils, accumulation of Fe(II) displaces many basic cations from the exchange complex, which increases the concentration of basic cations in porewater. Draining these soils removes basic cations from porewater, oxidizes Fe(II) to Fe(III), which results in the release of H+. In turn, the lower pH releases Al and other associated metals. Similarly, metals bound to sulfides can be directly released under drained conditions when sulfides are oxidized to sulfates, also resulting in the release of H+. Many other metals such as Ca, Mg, Cu, Zn, Pb, Hg, and Ni are not directly involved in oxidation–reduction reactions, but their solubilities are affected by changes in pH as a result of flooded and drained conditions.

20.9 Toxic Organics

Toxic organics are naturally occurring or synthetic chemicals, which at low concentrations have adverse effects on growth and activity of plants, animals, and/or microorganisms. Figure 20.27 shows the structures of some of the more common toxic organic compounds found in wetlands. Natural and constructed wetlands may receive toxic organics from a number of sources, including (1) direct applications to control aquatic weeds, algae and mosquitoes; (2) accidental spillage, surface runoff, and drainage water from agriculture, urban, and industrial sources; (3) domestic and industrial discharges into natural and constructed wetlands for wastewater improvement; (4) residual toxics remaining in agricultural soils that are converted to wetlands; and (5) in situ production by natural processes, mediated by plants and microorganisms.

These sources are likely to contribute vast amounts and multitudes of different types of toxic organics; however, widespread monitoring and toxicological studies have not been conducted to estimate the extent and consequences of contamination (Catallo, 1993). One estimate indicated that about 5000 wetlands and aquatic systems are impacted by agricultural pesticides in the United States (Cooper, 1993; Taraban et al., 1993). Many soil processes including microbial respiration, nitrification (Sayler et al., 1982), and cellulose and lignin degradation (McKinley et al., 1982; Katayama and Kuwatsuka, 1991; Dusek and Tesarova, 1996) are negatively impacted by toxic organics, and so pose a serious threat to proper functioning of wetland systems.

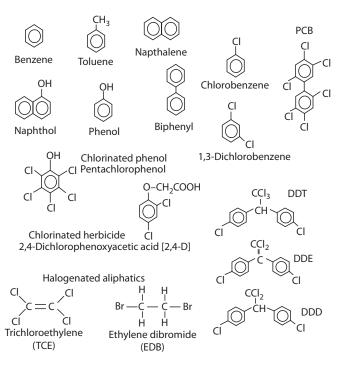

FIGURE 20.27 Basic chemical structures of common toxic organic compounds. (From Reddy, K.R., and R.D. DeLaune. 2008. Biogeochemistry of wetlands: Science and applications. CRC Press, Boca Raton, FL.)

Several processes regulate the fate of toxic organics once they enter wetlands, and most information about these processes has been gained through laboratory experiments that simulate wetland systems. In general, toxic organic compounds undergo similar transformation processes as natural organic matter, including aerobic and anaerobic microbial breakdown, vegetative uptake, volatilization, photolysis, abiotic oxidation and hydrolysis, bioaccumulation, sorption, and burial in the soil (D'Angelo, 2002). Through these processes, many wetlands are capable of attenuating this class of pollutants. However, the extent of these processes depends on the type of compound (water solubility, oxidation state, functional groups, molecular weight), as well as biological and chemical conditions in the soil-water column including pH, Eh, temperature, light intensity, nutrient and electron acceptor availability, type and amount of vegetation, organic matter content, and previous history of contamination. For a review of process models refer to Lyman (1982).

Microbial degradation is generally considered the main pathway for attenuation of toxic organics. This task is usually accomplished by sequential enzymatic reactions mediated by many populations working together, rather than by a single species. In wetlands with characteristically diverse populations of microorganisms ranging from aerobes to extreme obligate anaerobes, there is great potential for degradation of many types of chemicals. In many cases, these transformations are beneficial to microorganisms by reducing toxicity or by acting as C sources, nutrients or electron acceptors. Most enzymatic transformations can be grouped into four main categories: hydrolysis, oxidation, reduction, and synthesis. The type of enzymatic transformation involved depends mainly on the type of chemical and its functional groups, as well as environmental conditions that promote the activity of different enzyme systems. In wetland systems, a combination of reactions are typically required to attain complete mineralization of a chemical.

Extracellular enzymes produced by bacteria and fungi hydrolyze many types of toxic organics including organophosphates, phenoxyacetates, phenylureas, acid anilides, and phenylcarbamates (Burns and Edwards, 1980; Nannipieri and Bollag, 1991). Small molecular weight C, N, and P compounds released from these reactions provide nutrients for degrading populations. Monooxygenase or diooxygenase enzymes incorporate one or two atoms of O_2 into chemicals. Due to the requirement for O_2 , this reaction is largely limited to aerobic zones such as soilwater or root-soil interfaces. For alkanes and aromatics without functional groups (benzene and toluene), oxygenase activity is typically required before significant rates of degradation occur, which likely explains the recalcitrance of these chemicals in mostly anaerobic zones. Through oxidative reactions, many toxic organics are eventually utilized as C and energy sources by degrading populations (Figure 20.28). Monooxygenases and dioxygenases are less effective with highly oxidized chemicals, including highly chlorinated pentachlorophenol, 2,4,5 trichlorophenoxyacetic acid, hexachlorobenzene, polychlorinated biphenyls, carbon tetrachloride and tetrachloroethylene which

FIGURE 20.28 Depiction of the reactions and pathway in the complete oxidation of benzene to carbon dioxide and water. (From Reddy, K.R., and R.D. DeLaune. 2008. Biogeochemistry of wetlands: Science and applications. CRC Press, Boca Raton, FL.)

explains the recalcitrance of these chemicals under aerobic conditions. For these chemicals, reductive processes may be more effective microbial transformation processes.

Under extremely reduced conditions, electrons from organic matter and intermediate breakdown products (H2, fatty acids) can be transferred to toxic organics (Gibson and Sewell, 1992; Doong and Wu, 1995). These chemicals, therefore, function as electron acceptors, in which the reaction is coupled to energy generation for degrading populations using similar strategies that are used by aerobes and denitrifiers to gain energy from electron transfer to O₂ and NO₃-. These redox reactions are important in the process of reductive dehalogenation (Figure 20.29). Mohn and Tiedje (1991) found evidence that reductive dechlorination was beneficial to Desulfomonile tiedjei, which used 3-chlorobenzoate as an electron acceptor and was coupled to energy (ATP) production. The presence of alternate electron acceptors (O2, NO3-, SO42-) tends to inhibit reduction of toxic organics, since various microbial groups compete with each other for electron equivalents.

One drawback of reduction reactions is that they often result in production of intermediates that are also toxic. For example, D'Angelo and Reddy (2000) showed sequential reductive dechlorination of pentachlorophenol to 2,3,4,5-tetrachlorophenol to 3,4,5-trichlorophenol to 3,5-dichlorophenol to 3-chlorophenol. Complete degradation yielding CO_2 can be achieved if reductive conditions (necessary for dehalogenation) are combined with aerobic reactions (required to break the phenolic ring structure) (Figure 20.30). As toxic organics become reduced, they may more readily undergo oxidation reactions. Therefore, alternately flooding or draining soils, or planting O_2 -transporting plants, may promote mineralization compared to one process by itself.

FIGURE 20.29 Steps involved in the reductive dechlorination of pentachlorophenol.

FIGURE 20.30 Pathway of alternating reduction/oxidation steps involved in the complete oxidation of pentachlorophenol to carbon dioxide and water. (From Reddy, K.R., and R.D. DeLaune. 2008. Biogeochemistry of wetlands: Science and applications. CRC Press, Boca Raton, FL.)

Enhanced degradation by alternate anaerobic-aerobic soil processes has been shown for methoxychlor (Fogel et al., 1982).

In contrast to the above transformations that simplify chemical structures, synthesis reactions result in the addition of functional groups or the polymerization of compounds. Synthesis reactions can be beneficial as they can convert toxic organics into less toxic forms. For example, methylation of chlorophenols results in the production of volatile chloroanisoles, which likely benefits microorganisms by being less toxic (Neilson et al., 1983). Chloroanilines and phenolic compounds can also undergo oxidative coupling, or polymerization with soil humic substances through the enzymatic action of peroxidases, laccases, and tyrosinases (Burns and Edwards, 1980; Bollag and Liu, 1985; Sarkar et al., 1988; Lassen et al., 1994). Shindo and Huang (1984) demonstrated that polymerization of phenols could be abiotically catalyzed by Mn(IV), Fe(III), Al and Si oxides, which result in the formation of humic acids. An example of these types of reactions is shown in Figure 20.31. These processes are thought to be analogous to natural humic substance formation from lignin (polyphenols) and protein molecules (Allard et al., 1994; Pal et al., 1994). Synthesis reactions may also result in production of toxic organics in aquatic environments. For example, Asplund et al. (1993) characterized chloroperoxidases in soils that mediated production of chlorinated humic substances. Natural production of organically

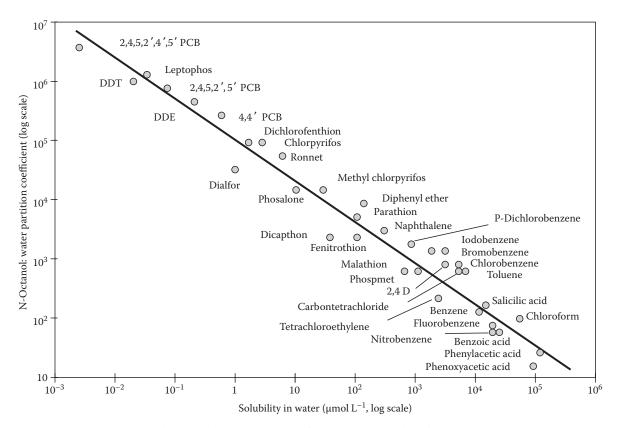

FIGURE 20.32 Relationship between the octanol–water partition coefficient and the solubility of various organic chemicals. (From Reddy, K.R., and R.D. DeLaune. 2008. Biogeochemistry of wetlands: Science and applications. CRC Press, Boca Raton, FL.)

bound chlorine, mediated by white-rot fungi, may partially explain the widespread genetic capacity of microorganisms to degrade man-made chemicals (Oberg et al., 1997).

Sorption to soils and sediments is an important hurdle in transformation processes, since it reduces the amount in the bioavailable (soluble) pool (Ogram et al., 1985; Mihelcic et al., 1993; Bouwer et al., 1994; D'Angelo and Reddy, 2003). Except in the case of extracellular enzymes, which have greater access to soil microsites, desorption and transport of toxic organics to microbial cells are prerequisites for transformation. Sorption to soil particles and organic matter is dependent on the characteristics of each toxic compound and can be described as a partitioning between the soil and water phases. The octanol:water partitioning coefficient is useful to characterize the sorption and solubility of various compounds (Figure 20.32). For strongly sorbed species, such as polychlorinated biphenyls and polyaromatic hydrocarbons with high octanol water partitioning coefficients, desorption may greatly curtail degradation kinetics (Manilal and Alexander, 1991). This process is important in many wetland soils because of accumulation of organic matter, and associated high cation exchange capacity, which promote hydrophobic partitioning and adsorption. Partial removal of toxic organics from the bioavailable pool through sorption may allow degradation to proceed at otherwise toxic levels (Apajalahti and Salkinoja-Salonen, 1984). On the other hand, anaerobic and neutral pH conditions tend to increase solubility of humic substances of wetland soils, which in turn enhances the solubility of toxic organics (Pardue et al., 1993).

21.1 Introduction

Acid sulfate soil materials are distinguished from other soil materials by having properties and behavior that have either (1) been affected considerably (mainly by severe acidification) by the oxidation of reduced inorganic sulfur (RIS) or (2) the capacity to be affected considerably (again mainly by severe acidification) by the oxidation of their RIS constituents.

A wide range of environmental hazards can be generated by the oxidation of RIS. These include (1) severe acidification of soil and drainage waters (below pH 4 and often <pH 3), (2) mobilization of metals (e.g., iron, aluminum, copper, cobalt, zinc), metalloids (e.g., arsenic), nutrients (e.g., phosphate), and rare earth elements, (3) deoxygenation of water bodies, (4) production of noxious gases (e.g., H_2S), and (5) scalding (i.e., devegetation) of landscapes. Some of these hazards are caused directly or indirectly by the severe acidification that can occur as a result of the oxidation of RIS, whereas some are not.

The properties and behavior of acid sulfate soils can impact detrimentally on infrastructure such as bridges, drains, pipes, roads—especially when constructed of steel and concrete. Waters draining from acid sulfate soil materials may be enriched in a wide range of potential toxicants, including metals and

metalloids, endangering aquatic life and public health. Crops, trees, pastures, and aquaculture may also be severely affected by acid sulfate soil materials. Acid sulfate soils can have detrimental impacts on their surrounding environments as well as on communities who live in landscapes containing these soils.

The assessment and management of acid sulfate soils often require an integration of knowledge from a wide range of disciplines including geochemistry, pedology, hydrology, toxicology, geomorphology, microbiology, geotechnical engineering, geology, agronomy, sedimentology, environmental health, and ecology. The complexities involved with their identification, assessment, classification, and management ensure that acid sulfate soils present a wide range of challenges for soil science.

21.2 Characteristics, Occurrence, and General Impacts

21.2.1 Characteristics

It is useful to distinguish between sulfidic soil materials that, if disturbed sufficiently, will become severely acidified, and sulfuric soil materials that have already become severely acidic as a result of the oxidation of RIS constituents.

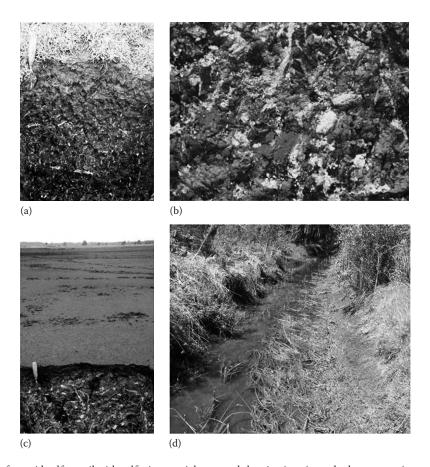

FIGURE 21.1 (a) Profile of an acid sulfate soil with sulfuric materials exposed showing jarosite and schwertmannite segregations. (b) Detail of yellow jarosite segregations in root channels (image width = 8 cm). (c) Profile of acid sulfate soil located in acid sulfate soil scald with sulfuric materials exposed. (d) Iron staining (by schwertmannite and goethite) of a drain in an acid sulfate soil landscape. The spade in (a) and (c) is 28 cm in length.

Sulfidic materials may be current or former marine and estuarine sediments, sediments in brackish lakes and lagoons, peats that originally formed in freshwater but have been inundated subsequently by brackish water, or accumulations of sediment in water bodies such as drains or wetlands affected by salinity (especially when sulfate is an appreciable component of that salinity). The required conditions for the formation and accumulation of RIS are (1) a supply of organic matter, (2) reducing conditions sufficient for sulfate reduction brought about by continuous waterlogging, (3) a supply of sulfate from tidewater or other saline ground or surface waters, (the sulfate is reduced to sulfides by bacteria decomposing the organic matter), and (4) a supply of iron from the sediment for the accumulation of iron sulfides, which make up the bulk of the RIS. Detailed discussions of the reactions that arise from these conditions are presented in Section 21.3.1 as well as in Chapter 27 of Handbook of Soil Sciences: Properties and Processes.

These conditions are found in tidal swamps and salt marshes where, over the last 10,000 years, thick deposits of sulfidic clay have accumulated in many locations around the globe (Pons and van Breemen, 1982; Dent and Pons, 1995). Figure 21.1a shows an acid sulfate profile highlighting the often characteristic yellow segregations of jarosite (KFe $_3$ (SO $_4$) $_2$ (OH) $_6$) and red–brown

segregations of schwertmannite (Fe $_8$ O $_8$ (OH) $_6$ (SO $_4$)) and goethite (α FeOOH) in the uppermost sulfuric layers. Sulfidic layers vary greatly in appearance but often have the gleyed colors typical of soil materials that are dominated by reduced waterlogged conditions.

It is significant that the distribution of RIS within the soil matrix of acid sulfate soils is not uniform; this both affects acid sulfate soil behavior and has implications for their management. Sandy and clayey acid sulfate soils often contain grains of pyrite (FeS₂) transported from elsewhere and deposited within the sediment. Subsequently, especially in slowly deposited clays, masses of framboids or individual crystals of FeS2 (e.g., Figure 21.2a and b) accumulate in situ in voids such as decomposing roots that provide both organic matter for bacterial decomposition and channels for the diffusion of SO₄²⁻ and dissolved Fe. Although the matrix may contain only relatively few embedded grains of pyrite, the network of neo-formed FeS2 may raise the overall concentration of pyrite to several percent on a soil dry mass basis. Where freshwater conditions have followed brackish tidal conditions, sulfidic soil materials may have been buried by peat or alluvium devoid of RIS (Diemont et al., 1993).

Disturbance of sulfidic soils by, for example, drainage or excavation often causes dramatic changes in the properties of these soil

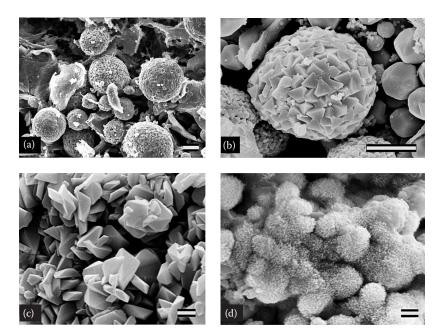

FIGURE 21.2 (a) Pyrite framboids in a root remnant of a sulfidic soil material. (b) Framboids and single crystals of pyrite in a void in a sulfidic material. (c) Jarosite crystals in a sulfuric soil material. (d) Segregations of schwertmannite with characteristic "ball and whisker" morphology. materials and the draining waters. If there are insufficient effective neutralizing materials (such as fine-grained calcium carbonate) in the sediment to neutralize the acidity generated by the oxidation of sulfides, extreme acidity can develop within weeks or months, resulting in sulfuric soil material (Figure 21.3). Sulfuric soil material is characterized by acidic pHs (e.g., pHs < 4), and usually presents yellow segregations of jarosite around pores and on ped faces (e.g., Figure 21.1b and c). Acid sulfate soils of peaty constitution usually do not have visible jarosite segregations, presumably

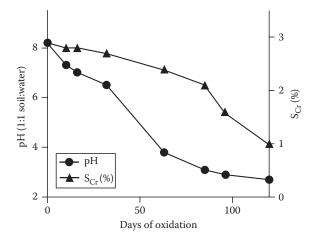

FIGURE 21.3 Typical change in S_{Cr} (mainly pyritic sulfur) and pH (1:1 soil:water) during moist oxidation of 10 mm thick slabs of a clayey gel-like sulfidic soil material from McLeods Creek in eastern Australia. (Modified from Ward, N.J., L.A. Sullivan, and R.T. Bush. 2004. Soil pH, oxygen availability and the rate of sulfide oxidation in acid sulfate soil materials: Implications for environmental hazard assessment. Aust. J. Soil Res. 42:509–514.)

because these soil materials contain only minor amounts of the phyllosilicate clays that act as the main source, upon acid dissolution, of the K⁺ that is necessary for jarosite precipitation.

Waters draining from acid sulfate soil landscapes can exhibit a range of colors and clarity. For example, they can be red/brown from precipitation of iron flocs, white from the formation of aluminum flocs (especially if the pH is suddenly increased, for example, by the introduction of drainage waters into tidal waters), blue-green from dissolved ferrous iron compounds, or crystal clear because low pH and Al^{3+} can effectively flocculate clays. In still-water conditions, the surfaces of acid sulfate soil-affected water-bodies can develop a brittle, iridescent film formed of iron-oxidizing bacteria. Acid sulfate soil drainage waters can often have pH < 3.5 and can be the cause of massive fish kills, the death of invertebrates and benthic organisms, the development of chronic fish diseases, and impaired fish recruitment (Sammut et al., 1993).

Acid sulfate soils can also present health hazards to people living in landscapes containing these soils. Ljung et al. (2009) found that acid sulfate soils could impact detrimentally on human health. The human health issues were related not only to the increased mobility of acid and metals from these soils affecting drinking water quality, food production and quality, but also to other issues such as increased dust generation, causing respiratory health issues and acidic pools of surface water in acid sulfate soil landscapes, providing suitable environments for mosquito breeding.

21.2.2 Occurrence

Estimates of the extent and distribution of acid sulfate soils globally suffer from scant field surveys, inadequate laboratory data, and also the lack of uniform, widely accepted definitions of these materials, as will be discussed later. Improvements in these areas have, however, led to better quantification of their extent and, in Australia at least, to better mapping of their distribution. Jennings et al. (1979) estimated the global extent of acid sulfate soil to be 15 million ha; 20 years later, this estimate was revised upward to 50 million ha (Ritsema et al., 2000). The recent Australian Atlas of Acid Sulfate Soils (Fitzpatrick et al., 2008) has greatly improved our understanding of the extent and distribution of acid sulfate soils within Australia.

The location of these soils is even more significant than their extent. Acid sulfate soils are often concentrated in otherwise densely settled coastal regions and floodplains where development pressures are intense and little suitable alternative land exists for the expansion of farming or urban and industrial development. As well as being commonly found in tropical regions (e.g., Vietnam, Thailand, Indonesia, Malaysia, and northern Australia), acid sulfate soils are also commonly found in temperate regions such as (e.g., the United States, Scandinavia, and southern Australia).

Although acid sulfate soils are often thought of as almost exclusively a coastal issue, acid sulfate soils are also widely distributed in inland areas wherever the general conditions for RIS formation—a ready source of sulfate, iron, and organic matter in reducing waterlogged sediments—are met. In Australia, the large areas affected by human-induced salinity, caused by overclearing of trees and suboptimal irrigation practices, have also often been found to be areas affected by the contemporary formation of acid sulfate soil materials (Fitzpatrick et al., 1996; Sullivan et al., 2002; Fitzpatrick et al., 2009).

There is significant spatial variability in the distribution and properties of acid sulfate soils from the microscale (as discussed previously for the distribution of pyrite in relation to soil microstructure) to the regional scale. Dent (1986) gives examples of soil patterns at different scales that have been unearthed by soil surveys. Surveying acid sulfate soils in tropical tidal environments is often arduous and enlivened by mosquitoes and crocodiles: accordingly, remote sensing has been widely used for these activities.

Quantitative methods of analysis are required to support soil survey programs and to provide essential data for modeling the likely response of the land to management options. The required analyses must either be performed in a timely fashion before gross chemical changes take place, or the samples must be preserved quickly by methods such as rapid oven drying or ideally freezing, otherwise, the pH may fall markedly to <4, within days or weeks.

The methods of sampling, sample preparation, and analysis of acid sulfate soil materials vary widely according to the purpose of the study and the corresponding properties required. The methods of analysis vary from standard wet chemical methods [an authoritative, readily available reference for these methods is Ahern et al. (2004)], standard soil physical methods for properties such as texture, hydraulic conductivity, and bulk density, to x-ray diffraction, x-ray fluorescence, analytical electron microscopy, through to advanced synchrotron-based techniques. In terms of management of acid sulfate soil materials,

the acid-base accounting approach (see Section 21.7.2.3) has significant advantages over other routine analytical approaches as it allows ready quantification of the acidity hazard, necessary for the rational determination of liming rates and for verification of management practices (Ahern et al., 2004).

21.3 Characteristic Minerals and Geochemical Processes

21.3.1 Reduction Processes

A defining characteristic of sulfidic acid sulfate soil materials is the presence of significant concentrations of RIS. RIS include iron disulfides (most commonly pyrite (FeS₂) (Bloomfield and Coulter, 1973; Pons, 1973; van Breemen, 1973), and generally lower amounts of other minerals such as monosulfides (Georgala, 1980; Bush et al., 2000), greigite (Fe₃S₄) (Bush and Sullivan, 1997), and elemental sulfur (S₈) (Burton et al., 2006a, 2006b).

The vast majority of RIS in sulfidic acid sulfate soil materials have formed at earth-surface temperatures and pressures under waterlogged, anoxic conditions. Under such conditions, accumulation of RIS species depends on microbially mediated sulfate reduction, which is itself dependent on organic carbon availability, supply of sulfate, and the amount of competing electron acceptors, including reactive Fe^{III}-minerals (Fanning et al., 2002). These variables influence the activity of dissimilatory sulfate-reducing microorganisms, which include phylogenetically diverse anaerobes that oxidize simple organic compounds or hydrogen using sulfate as an electron acceptor. The overall process of dissimilatory sulfate reduction can be shown, for example, by

$$CH_2COO^- + SO_4^{2-} + H^+ \rightarrow H_2S + 2HCO_3^-$$
 (21.1)

During this process, the sulfur in sulfate is reduced from the S^{6+} oxidation state to S^{2-} . Conditions that are conducive to microbially mediated sulfate reduction include organic-rich coastal and estuarine sediments, such as in tidal marshes and swamps. In such systems, tidal exchange of pore-water supplies sulfate and removes the resultant HCO_3^- produced via the reaction in Equation 21.1. Tidal flushing thereby prevents the accumulation of pore-water alkalinity. In iron-deficient systems, this tidal flushing can also remove pore-water H_2S and lead to its subsequent oxidation to elemental S (and eventually to sulfate).

In contrast, in soils containing appreciable Fe^{2+} , often produced by ferric iron reducing microorganisms, H_2S may react rapidly to form monosulfide (FeS) precipitates as below:

$$H_2S + Fe^{2+} \rightarrow FeS + 2H^+$$
 (21.2)

The initial FeS phase to form by reaction between H_2S and Fe^{2+} (Equation 21.2) has proved difficult to characterize, even in well-defined synthetic studies (Rickard and Morse, 2005). Recently, such studies have shown that nanoparticulate mackinawite (tetragonal FeS) is the first condensed phase to

FIGURE 21.4 Transmission electron diffraction pattern and micrographs showing nanoparticulate mackinawite in monosulfidic soil materials. (Image adapted with permission from Burton, E.D., R.T. Bush, L.A. Sullivan, R.K. Hocking, D.R.G. Mitchell, S.G. Johnston, R.W. Fitzpatrick, M. Raven, S. McClure, and L.Y. Jang. 2009. Iron-monosulfide oxidation in natural sediments: Resolving microbially mediated S transformations using XANES, electron microscopy, and selective extractions. Environ. Sci. Technol. 43:3128–3134. Copyright 2009 American Chemical Society.)

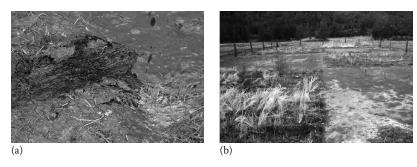

FIGURE 21.5 (a) Accumulation of monosulfidic black ooze (MBO) showing the black gel-like MBO after the overlying brown oxidized surface layer has been removed (field of view width is 35 cm). (b) A field trial on an acid sulfate scald showing successful early revegetation in plots treated by a combination of liming, ridging, mulching and stock exclusion.

form through this reaction. In acid sulfate soil materials the occurrence of mackinawite as 5–30 nm nanoparticles has been only recently demonstrated (Figure 21.4) (Burton et al., 2009). The strong black color characteristic of these acid sulfate soil materials (e.g., the monosulfidic black ooze in Figure 21.5a) is largely due to the presence of nanoparticulate mackinawite (Burton et al., 2009).

The $\rm H_2S$ produced by microbial sulfate reduction can also react with Fe^{III} contained in ferric oxide and oxyhydroxide minerals such as goethite, to produce elemental sulfur:

$$H_2S + 2FeOOH + 4H^+ \rightarrow 0.125 S_8 + 2Fe^{2+} + 4H_2O$$
 (21.3)

The Fe^{2+} produced via this reaction may then feed into the reaction described by Equation 21.2, thus also resulting in mackinawite formation. This overall process, termed "sulfidization" can be represented as

$$3H_2S + 2FeOOH \rightarrow 0.175S_8 + 2FeS + 4H_2O$$
 (21.4)

In the presence of an oxidant, such as O₂, mackinawite is unstable and can transform readily via a solid-state process to greigite

$$4\text{FeS} + 0.5\text{O}_2 + 2\text{H}^+ \rightarrow \text{Fe}_3\text{S}_4 + \text{Fe}^{2+} + \text{H}_2\text{O}$$
 (21.5)

Although frequently mentioned, there are only few studies (e.g., Bush and Sullivan, 1997) that conclusively document the occurrence of greigite in acid sulfate soil materials. On the basis of the limited amount of field data, it appears that greigite occurrence is limited to the oxidation front in mildly acidic soils that are subject to an oscillating groundwater table. Mackinawite and greigite are often described as "iron-monosulfide" minerals because they have Fe:S ratios that are close to 1:1 (Rickard and Morse, 2005). These mineral species are measured analytically by their dissolution in HCl to yield H₂S gas and described as acid volatile sulfide (AVS).

Both mackinawite and greigite have long been implicated as precursors to the formation of iron disulfides such as pyrite and marcasite. For example,

$$Fe_3S_4 + 2H^+ \rightarrow 2FeS_2 + Fe^{2+} + H_2$$
 (21.6)

Pyrite can also form without the need for precursory greigite via (1) mackinawite oxidation by polysulfide species (Rickard, 1975; Luther, 1991) and (2) mackinawite oxidation by H_2S (Rickard, 1997; Rickard and Luther, 1997). These two pathways of pyrite formation, which involve an intermediate dissolved FeS cluster complex, can be represented overall as

Polysulfide pathway

$$FeS + S_n^{2-} \rightarrow FeS_2 + S_{n-1}^{2-}$$
 (21.7)

Hydrogen sulfide pathway

$$FeS + H_2S \rightarrow FeS_2 + H_2 \tag{21.8}$$

Although iron monosulfides are widely believed to be an essential precursor to pyrite formation, this is not necessarily always the case. Pyrite can form quite rapidly in the presence of suitable reactive surfaces such as bacterial surfaces (Canfield et al., 1997) that serve to overcome a significant supersaturation threshold by providing heterogeneous nucleation sites. Other suitable reactive surfaces include preexisting pyrite crystals or organic substrates such as plant material. Accumulation of pyrite in soil can occur rapidly under suitable field conditions (Howarth, 1979; Rosicky et al., 2004a).

Pyrite is by far the most commonly observed RIS species in sulfidic acid sulfate soil materials. In these materials, pyrite presents a range of distinct crystal morphologies (e.g., Figure 21.2a and b). The most remarkable of these morphologies are framboids (from the French term for raspberry—frambois). Pyrite framboids consist of spheroidal aggregates of densely packed, individual microcrystals. Earlier research into the origin of pyrite framboids in sediments pointed toward either a bacterial influence or the magnetic aggregation of precursor greigite crystals. However, it now seems that the formation of framboids is more likely a function of the degree of solution supersaturation with regard to pyrite.

While pyrite is normally the most abundant iron disulfide in acid sulfate soil materials, marcasite (orthorhombic FeS₂) may occur in specific situations. Acidic conditions (pH < 6) are required for the initial formation of marcasite instead of pyrite. Such conditions occur in waterlogged soils and sediments that are rich in dissolved organic acids, capable of buffering the low pH. For example, marcasite is a common iron sulfide in some peaty acid sulfate soil materials in eastern Australia (Bush et al., 2004a).

21.3.2 Oxidation Processes

Pyrite and the other iron-sulfide minerals persist in soils only under anoxic, waterlogged conditions. If these conditions become oxic by, for example excavation of the soils, the iron-sulfide components can undergo a series of oxidation reactions. For example, in the presence of oxygen (and water) pyrite oxidizes to ultimately yield sulfuric acid and a poorly soluble Fe^{III} precipitate:

$$FeS_2 + 3.75O_2 + 3.5H_2O \rightarrow Fe(OH)_3 + 4H^+ + 2SO_4^{2-}$$
 (21.9)

While this reaction shows that exposure to oxygen under moist conditions is the driving force for pyrite oxidation, it neglects the great complexity of reaction steps in the overall oxidation process. This complexity includes a number of possible final iron phases as well as the formation of intermediate sulfoxy anions and elemental S. Some of the more important S transformations occurring during pyrite oxidation are shown in Figure 21.6.

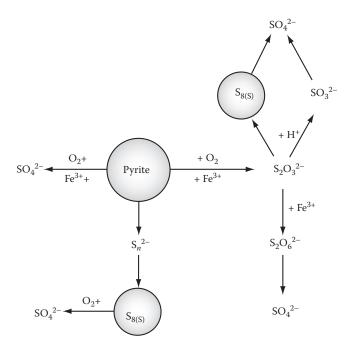

FIGURE 21.6 Conceptual model showing sulfur transformations during pyrite oxidation. (Modified from Druschel, G.K., Baker, B.J., Gihring, T.H., and Banfield, J.F. 2004. Acid mine drainage biogeochemistry at Iron Mountain, California. Geochem. Trans. 5(2):13–32.)

Chemolithotrophic Fe- and S-oxidizing bacteria play an important role in mediating various steps in the overall oxidation process, and in determining the formation and persistence of intermediate S species.

A conceptual model of iron behavior during the pyrite oxidation process is presented in Figure 21.7. This model highlights the wide variety of potential phases that play a role in determining the iron biogeochemistry following pyrite oxidation. Ferrous iron released in the initial stages of pyrite oxidation

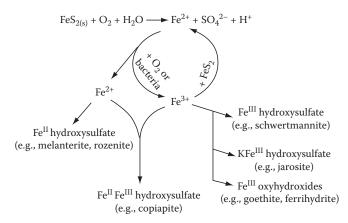

FIGURE 21.7 Conceptual model of iron transformations during and following pyrite oxidation. (Adapted from Rose, A.W., and C.A. Cravotta, III. 1998. Geochemistry of coal mine drainage, p. 1–1, 1–22. *In* K.B.C. Brady, M.W. Smith, and J. Sehueck (eds.) Coal mine drainage prediction and pollution prevention in Pennsylvania. PA Department of Environmental Protection: Commonwealth of Pennsylvania, Harrisburg, PA. 5600-BK-DEP2256.)

may precipitate as Fe^{II} hydroxysulfate minerals (Fanning et al., 2002), most importantly melanterite, rozenite, and szomolnokite. These phases are readily soluble and are rarely observed in acid sulfate soil materials.

Under continuation of oxidizing conditions, the Fe^{2+} released by pyrite oxidation is also subject to oxidation to Fe^{3+} . While the simple oxidation process consumes some acidity, the subsequent hydrolysis of the resulting Fe^{3+} leads to the liberation of acidity. At low pH (e.g., <4), Fe^{3+} is sufficiently soluble that it may serve as a very effective electron acceptor driving further pyrite oxidation (Moses et al., 1987). For this reason, it has been often suggested that the rate of Fe^{2+} oxidation to Fe^{3+} may be the ratedetermining step in pyrite oxidation.

Partial oxidation of Fe^{2+} to Fe^{3+} can lead to precipitates of mixed valence Fe salts, such as copiapite. This phase is one of the "soluble salts" that may form in acid-sulfate soils under prolonged dry conditions (Fanning et al., 2002). Dissolution of these minerals during rainfall events may cause a first-flush of stored acidity.

The Fe³+ produced via pyrite oxidation also commonly precipitates as a range of FeIII-bearing minerals. In acid sulfate soil conditions at pH < 3, and/or in the presence of abundant K+, jarosite appears to be the predominant FeIII phase, whereas in the pH range of 3–4, schwertmannite is an important FeIII phase in acid-sulfate soil landscapes (Bigham et al., 1992; Sullivan and Bush, 2004). The widespread occurrence of schwertmannite in acid-sulfate soils has only been confirmed relatively recently (Sullivan and Bush, 2004). Schwertmannite has poor crystallinity and often presents a "ball-and-whisker" micromorphology (Figure 21.2d).

Schwertmannite is metastable and over time transforms, via dissolution-reprecipitation, to form a range of Fe^{III} oxyhydroxides (Bigham et al., 1996). These include ferrihydrite, lepidocrocite, and goethite, with the latter being most stable. The transformation of schwertmannite (an Fe^{III} oxyhydroxysulfate) to these Fe^{III} oxyhydroxides involves the hydrolysis of Fe³⁺and the liberation of acidity. As a consequence, schwertmannite transformation can suppress pH long after the initial source of acidification (i.e., pyrite) has been consumed.

The type of secondary minerals formed from the Fe released during pyrite oxidation determines, to a large extent, the amount of acidity expressed (Dold, 2003; Dold and Fontbote, 2001). For example, if the released Fe precipitates as goethite or ferrihydrite from the Fe3+ produced by sulfide oxidation, then 3.0 mol of H+ are formed for every mole of Fe3+ hydrolyzed from pyrite. However, if hydrolysis is incomplete and jarosite is formed, only around 2 mol of H+ is released for every mole of Fe3+ hydrolyzed from pyrite (van Breemen, 1976). If schwertmannite is formed, then approximately 2.575 mol of H⁺ is released for every mole of Fe³⁺ hydrolyzed from pyrite (Piene et al., 2000). The "stored" acidity in these two minerals is important as the Fe in both jarosite and schwertmannite can undergo further hydrolysis and result in the release of acidity into the surrounding environment (Dold, 2003; Dold and Fontbote, 2001; Sullivan and Bush, 2004).

21.3.3 Pyrite Oxidation Rates

The oxidation of FeS2 depends on factors including the supply of O2, the availability of water, and the physical properties of FeS₂. Pyrite oxidation generates acid and releases heat; consequently, the acidity and temperature of the surrounding solution will affect the overall reaction rates. The oxidation of FeS₂ in the environment is usually ultimately determined by the supply of O₂. Models describing FeS₂ oxidation are often based on the assumption that all other constituents required for the oxidation process are freely available except for O2, which is supplied through the porous material from the atmosphere (Dent and Raiswell, 1982; Davis and Ritchie, 1986; Pantelis and Ritchie, 1991; Bronswijk et al., 1993). The rate of pyritic oxidation is often assumed to be a linear function of the dissolved O2 concentration (Bartlett, 1973; Braun et al., 1974) but the Michaelis-Menton equation has also been adopted (Liu et al., 1987; Tan, 1996).

Temperature, which influences both chemical and microbial oxidation, is an important factor in determining the oxidation rate of pyritic materials. Biological oxidation only occurs between 0°C and 55°C (optimum 25°C-45°C) (Lundgren and Silver, 1980) but chemical oxidation can take place above this temperature. Jaynes et al. (1984) modeling acid generation in mine spoil, took account of rates of diffusion of both O2 and Fe³⁺ and also the activity of the bacteria generating Fe³⁺, which was estimated from available energy and deviations from ideal temperature, solution pH and O₂ concentration. Pantelis and Ritchie (1992) introduced a ceiling temperature (100°C), above which microorganisms cease to be effective as catalysts in FeS2 oxidation. The influence of temperature on oxidation rate follows the empirical Arrhenius equation (Ahonen and Tuovinen, 1991). Because the pyritic oxidation reaction is exothermic, temperature rises depending on the rate of reaction and thermal properties of the bulk soil. In acid sulfate soils, temperature profiles might be used to determine pyritic oxidation rates but because pyritic layers are typically shallow (1-2 m below the surface), distinguishing between the calorimetric contribution from pyritic oxidation and solar radiation may prove difficult.

21.4 Modeling Soil Physical and Chemical Processes in Acid Sulfate Soils

Soil and water management are the key factors for sustainable use of acid sulfate soils in agricultural landscapes and natural habitats. Numerous complex physical and chemical processes contribute to the genesis of acid sulfate soils and determine the magnitude and rates of acidification or neutralization and the production/mobilization of (toxic) compounds. Because of this complexity, prediction of the effects of soil and water management and their practical consequences are only feasible by using simulation models. SMASS is one model for acid sulfate soils.

The SMASS model is described in detail in AARD/LAWOO (1993), Bronswijk and Groenenberg (1993), and Ritsema and Groenenberg (1993).

The SMASS model consists of a number of mutually linked submodels in which the various physical and chemical processes occurring in acid sulfate soils are described mathematically. To solve these equations, the soil profile is divided into compartments that may be of variable size. The initial physical and chemical conditions in each compartment and values for the boundary conditions must be given as model inputs for the complete simulation period. The physical and chemical conditions in each compartment, together with the water and solute fluxes at the boundary of the soil system are computed at selected time intervals in the following sequence: (1) The water transport submodel computes vertical water transport, giving the water content profile that complements that of air. (2) In the O2 transport and FeS2 oxidation submodel, air contents are used to compute O₂ diffusion coefficients in the air-filled macropores. Oxygen consumption values in the soil are calculated from FeS₂ and organic matter contents, and subsequently, the O₂ content profile in the macropores is computed. (3) Depending on the O₂ concentration at a given depth, the rate of FeS₂ oxidation at that depth is calculated in the O₂ transport and FeS₂ oxidation submodel. For each depth, the oxidized amount of FeS₂ is converted into amounts of H+, Fe3+, and SO42- produced, with the remaining FeS₂ being used for calculations in the next time-step. (4) The solute transport submodel computes solute fluxes between soil compartments in accordance with the calculated water fluxes (from step 1). (5) In the chemical submodel, first the production/ consumption terms for the nonequilibrium processes (such as Fe reduction) are calculated. Then the total concentrations of each chemical component are calculated in the soil compartments by summing the production/consumption terms, the inflow/ outflow (from step 4), and the total amounts at the end of the previous time-step for each component. From these total concentrations, the equilibrium concentrations in the soil solution, the composition of the exchange complex, and the amount of minerals and precipitates are computed for each compartment.

Time-steps for computations of the water and solute transport submodels are in the order of hours. Pyrite oxidation, $\rm O_2$ profiles, and chemical equilibria are computed once every day. The output of the SMASS model and its submodels is generally given on a daily basis. Model predictions can be carried out for one or more decades, so that the long-term effects of various water management strategies can be evaluated quantitatively.

21.5 Hazards Arising from Acid Sulfate Soil Disturbance

21.5.1 Acidification

Oxidation of RIS is the primary cause of the extreme acidification that characterizes sulfuric acid sulfate soil materials. By definition, the pH of sulfuric acid sulfate soil is <pH 4 (or <3.5 according to the particular soil taxonomy being employed)

but values of pH < 3 in actively oxidizing soils are frequently observed (Dent, 1986). Such extreme acidification significantly alters the soil chemistry, often rendering it hostile to plants and can create a source of contamination to groundwater and surface water run-off. The acid produced can react with clay minerals and oxides to release silica and metal ions, principally, aluminum, iron, potassium, sodium, and magnesium (Nriagu, 1978). Other metal and metalloid ions can also be released (van Breemen, 1973; Sammut et al., 1996b; Åström, 2000).

The impacts of severe acid sulfate soil acidification on agricultural crops have been well documented (Dent, 1986). Many crop plants are highly sensitive to low pH soil conditions and acidification can greatly reduce yields and, in extreme cases, cause complete crop failure. In addition, the formation of acidic secondary iron minerals such as jarosite and schwertmannite can significantly reduce the availability of nutrients such as phosphorus and nitrogen. Farmers have tried many different approaches to ameliorate acidity by techniques, such as the addition of neutralizing agents, other soil amendments, organic mulch, and reconfiguring plant beds to enhance the leaching of acidic products from the soil (Dent, 1986). Success in cropping acid sulfate soil landscapes is mixed and highly dependent on the initial degree of acidification and capacity of the specific crop types to tolerate acidic conditions. Acidity severely constrains farming on acid sulfate soils with some exceptions (White et al., 1997).

Aluminum toxicity is a significant issue linked to acid sulfate soil acidification for terrestrial plants (Dent, 1986) and downstream aquatic flora and fauna (Sammut et al., 1996a, 1996b). The solubility of Al is critically dependent on pH, only becoming soluble at environmentally significant levels at approximately pH < 5. Soluble Al affects plant growth primarily by disrupting root function and is a major concern for food production and agricultural income for rural and regional communities. Severe environmental impacts can occur when acidic Al-rich leachate from acid sulfate soil enters water bodies. The more acute ecological impacts of acid sulfate soil acidification in waterways include fish kills (Sammut et al., 1996a, 1996b; Callinan et al., 2005), loss of native aquatic macrophytes and fauna followed by invasion by acid tolerant species (Sammut et al., 1996a), mass mortality of crustaceans and shell fish (Simpson and Pedini, 1985), and loss of benthic communities (Corfield, 2000). Sublethal exposure of fish to acidity has also been linked to an increased susceptibility to skin diseases (Callinan et al., 2005), whereas depletion of alkalinity has been linked to poor shell development in crustaceans (Dove and Sammut, 2007).

A range of potentially longer-term impacts on aquatic ecosystems arising from acid sulfate soil leachate include disturbance to fish reproduction and recruitment, acidity barriers to fish migration, decline of primary food web, reduction of species diversity, and long-term habitat degradation (Sammut et al., 1996a, 1996b). In assessing the likely impacts of acid sulfate soil acidification on downstream aquatic environments, it is necessary to consider the vulnerability of the aquatic ecosystems, the

duration and frequency of acidification episodes, and the potential intensity of acidification based on the properties and quantities of the acidic leachate.

21.5.2 Iron Mobilization

As shown in Figure 21.7, Fe²⁺ is a primary product of pyrite oxidation. At high pH values (pH > 7), Fe²⁺ is chemically rapidly oxidized to Fe³⁺ (Cornell and Schwertmann, 2003). At much lower pHs (i.e., pH < 4.5), the oxidation of Fe²⁺ to Fe³⁺ is catalyzed by acidophilic lithotrophic bacteria such as *Acidithiobacillus ferroxidans* (Pronk and Johnson, 1992), *Thiobacillus ferroxidans*, and *Leptospirillium ferroxidans* (Johnson, 1993). The oxidation of Fe²⁺ has direct environmental consequences arising from the liberation of acidity and the formation of secondary iron minerals that can control soil and water geochemistry.

Accumulations of iron minerals are ubiquitous in acid sulfate soil landscapes. The precipitation and mineralogy of secondary iron minerals has been reviewed elsewhere in this chapter and in detail by Alpers and Nordstrom (1999) and Cornell and Schwertmann (2003).

Understanding the types of iron precipitates that form in acid sulfate soil landscapes during oxidation is important as particular iron mineral phases can exercise a major influence on the environment (e.g., Dold and Fontbote, 2001; Sullivan and Bush, 2004). In a study of surface iron precipitate accumulations associated with waterways in acid sulfate soil landscapes, Sullivan and Bush (2004) found that schwertmannite was the dominant secondary iron mineral. The schwertmannite occurred as coatings on vegetation, accumulations in low depressions, and iron flocs adhering to surfaces in acidified waterways. The potential acidity within the schwertmannite was high, ranging between 1900 and 2580 mol (H+) t-1, indicating that the schwertmannite was a substantial intermediate store of acidity within these acid sulfate soil landscapes. The retained acidity within both schwertannite and jarosite have recently been included into the quantitative assessment of the net acidity of sulfate soil materials (Ahern et al., 2004).

Iron precipitates in the form of iron flocs within the water column also are known to directly affect gilled organisms, smother benthic communities and aquatic flora (Sammut et al., 1996a, 1996b), diminish the aesthetic values of recreational waterways, and threaten estuarine and marine environments (Powell and Martens, 2005). The accumulation of iron flocs has also been linked to contemporary sulfur cycling and the formation of monosulfidic black ooze (MBO) accumulations in acid sulfate soil affected waterways (Figure 21.8).

21.5.3 Other Metal and Metalloid Mobilization

Mobilization of metals and metalloids to soil porewaters from acid sulfate soil can constitute a major environmental hazard (e.g. Åström et al., 2001; Burton et al., 2006c; Burton et al., 2008). Metals that have been reported at levels exceeding accepted environmental protection thresholds in acid sulfate

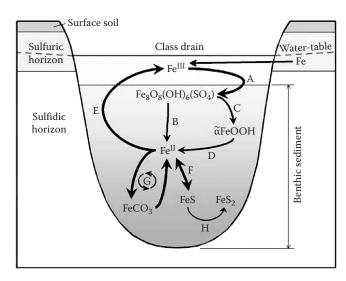

FIGURE 21.8 Conceptual model of in situ Fe transformations in accreting coastal lowland acid sulfate soil (class) waterways. (A) precipitation of schwertmannite (Fe₈O₈(OH)₆(SO₄)), (B) reductive dissolution of schwertmannite, (C) transformation of schwertmannite to goethite (α̃FeOOH), (D) reductive dissolution of goethite, (E) upward diffusion and oxidation of Fe²⁺, (F) precipitation–dissolution of disordered mackinawite (FeS), (G) regulation of porewater Fe²⁺ via precipitation–dissolution of siderite (FeCO₃), (H) and formation of pyrite (FeS₂; kinetically retarded due to high pore-water Fe²⁺ concentrations). (After Burton, E.D., R.T. Bush, and L.A. Sullivan. 2006d. Sedimentary iron geochemistry in acidic waterways associated with coastal lowland acid sulfate soils. Geochim. Cosmochim. Acta 70:5455–5468. Copyright (2006d), with permission from Elsevier.)

soil include Al, As, Ba, Cd, Co, Cr, Cu, Fe, Mn, Ni, Pb, Sb, V, Zn (e.g., Åström et al., 2001; Macdonald et al., 2004a; Burton et al., 2006c). Metals in natural soils occur within mineral phases or as ions or ionic complexes sorbed to reactive surfaces (Åström, 1998; Faltmarsch et al., 2008; Claff et al., 2010). Acidification greatly enhances the solubility of many metals, promoting their subsequent release from mineral phases by dissolution or cation exchange. The pH dependence of metal release has received considerable attention (Sammut et al., 1996b; Wilson et al., 1999; Åström, 2001; Preda and Cox, 2001; Macdonald et al., 2004a; Simpson et al., 2010), and there are strong similarities in metal release within acid sulfate soil and acid mine drainage systems (Evangelou and Zhang, 1995).

Numerous studies have documented the impacts from soluble metals on crop production (e.g., Dent, 1986), terrestrial habitats (van Breemen, 1973), and more recently, attention has turned to their impact on aquatic environments (Sammut et al., 1996a, 1996b; Wilson et al., 1999; Johnston et al., 2004; Callinan et al., 2005). Gilled organisms are particularly vulnerable to soluble metals and metal mobilization can lead to rapid mortality rates in these species (Simpson and Pedini, 1985; Sammut et al., 1993; Sammut et al., 1996a, 1996b). Studies of the effects of metals on shellfish (oysters) revealed longer-term, chronic impacts on their growth and survival (Dove and Sammut, 2007). However, the longer-term impacts of metal release from

acid sulfate soils to surrounding aquatic environments are poorly understood. Although elevated metal concentrations can be toxic to both aquatic flora and fauna, the consequences of these conditions to algal and phytoplankton production are largely unknown, as is the potential for their bioaccumulation (Macdonald et al., 2004a).

Most reports on the impacts arising from metal release from acid sulfate soil focus on the consequences of metal mobilization under oxic-acidifying conditions. However, metals can also be mobilized when sulfuric acid sulfate soils are subject to prolonged inundation, resulting in the development of anoxic reducing conditions. Acid sulfate soil occurs in low-lying floodplain environments and, therefore, is subject to periodic water logging and oscillating redox conditions. The processes of metal mobilization and behavior of metals are very different under these conditions. The behavior of iron and arsenic are good examples of metal and metalloid mobilization from acid sulfate soil materials following inundation. Accumulations of iron minerals in acid sulfate soils are often concentrated near the ground surface and include goethite, ferrihydrite, jarosite, and schwertmannite. These iron minerals often have a large surface area and are a significant sink for the sorption of metals. Under reducing conditions, these iron oxides are prone to microbial reductive dissolution (van Breemen, 1973; Burton et al., 2007). Microbial iron reduction triggers three major changes that affect metal mobilization. First, it results in the dissolution of Fe³⁺and transformation to Fe2+, causing the corelease of other metals sorbed to the Fe mineral surfaces. Secondly, the microbial reduction process is proton-consuming and, when accompanied by the formation of bicarbonate as a by-product of microbial respiration, can result in an in situ neutralization (Blodau, 2006). The increase in porewater pH generally reduces the solubility of divalent metals and aluminum. Finally it also facilitates the recently identified Fe2+ catalyzed transformation of poorly crystalline iron oxide minerals to more crystalline phases (e.g., rapid transformation of schwertmannite to goethite). Although the overall consequences of these rapid mineral transformations on metal mobility are yet to be quantified (Burton et al., 2010), the mobility of some metals and metalloids can increase under these conditions. For example, arsenic is most soluble at around pH 5 and when associated with iron oxides in acid sulfate soil materials, it is readily mobilized at the onset of microbially mediated iron reduction (Burton et al., 2008). Arsenic contamination of groundwater and surface water is occurring as the result of such processes in acid sulfate soil landscapes (e.g. Johnston et al., 2010). It is important to recognize that metals and metalloids can have a significant impact in acid sulfate soil landscapes not only (1) when acid sulfate soil is allowed to oxidize and acidify, but (2) also following the prolonged inundation of previously oxidized, iron-enriched acid sulfate soil.

21.5.4 Deoxygenation of Water Bodies

Acute deoxygenation of estuaries, lakes, rivers, and drainage channels is a major contributor to catastrophic fish kills

(Hamilton et al., 1997; Johnston et al., 2003; Howitt et al., 2007). Many potential factors contribute to deoxygenation events, and they are known to impact a very wide range of environments. Severe deoxygenation of waterways within acid sulfate soil landscapes has been linked directly to the behavior of acid sulfate soil materials (e.g., Sullivan and Bush, 2000).

Deoxygenation results when solids and aqueous compounds with a capacity to react with dissolved oxygen, enter water bodies and consume oxygen more rapidly than it can be replenished. The magnitude of deoxygenation depends on the spatial scale of the event, its persistence and its intensity. Aquatic ecosystems require dissolved oxygen concentrations generally greater than 85% saturation for lowland rivers (e.g., ANZECC/ARMCANZ 2000). Native fish and other large aquatic organisms are known to survive on dissolved oxygen concentration of as little as 2 mg L⁻¹, but may become stressed below 4–5 mg L⁻¹ (Hladyz and Watkins, 2009). In recent studies of a major estuarine river system in eastern Australia affected by deoxygenation, Wong et al. (2010) found deoxygenation was confined to downstream of acid sulfate soil affected waterway confluences and occurred during the later phase of the flood recession.

Anaerobic decomposition of floodplain vegetation in backswamps can be a primary process leading to the deoxygenation of large volumes of waters in acid sulfate soil landscapes (Johnston et al., 2003; Wong et al., 2010). Decomposition of flood-intolerant vegetation in drained acid sulfate floodplains can lead to the formation of "blackwater"-a colloquial term used to describe anoxic stagnant floodplain water that develops a distinctive dark color as a result of the accumulation of dissolved organic carbon compounds. Blackwater is typically anoxic, has a high chemical oxygen demand (COD) and high dissolved Fe concentrations, and rapidly consumes dissolved oxygen when it discharges to main water bodies (Johnston et al., 2003). Extensive floodplain drainage networks in acid sulfate soil areas can significantly enhance the transport of hypoxic backswamp blackwater to main river channels, thereby enhancing the magnitude and duration of consequent estuarine deoxygenation.

The propensity for MBO to accumulate and be mobilized by floodwaters in drainage channels has also been identified as a contributing factor to deoxygenation in acid sulfate soil areas (Sullivan et al., 2002; Bush et al., 2004b, 2004c; Burton et al., 2006b, 2006d).

The chemistry of estuarine waters during hypoxic events has indicated elevated concentrations of redox sensitive species associated with acid sulfate soil (e.g., Fe²⁺, dissolved Mn, and elemental sulfur) (Wong et al., 2010), further implicating acid sulfate soil and MBO materials as a cause of deoxygenation.

The role of MBO in deoxygenation and latter acidification in acid sulfate landscapes has only recently been discovered (Sullivan et al., 2000, 2002). Burton et al. (2006c) have described the oxidation dynamics of MBO when mobilized into oxygenated water. A summary of the changes in sulfur speciation (i.e., pyrite, iron monosulfide (FeS) elemental sulfur and sulfate) and pH during such MBO oxidation is shown in Figure

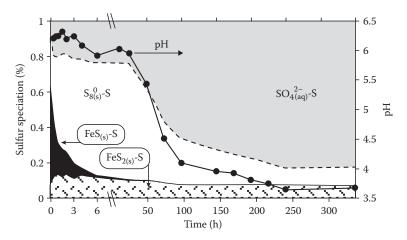

FIGURE 21.9 Changes to the sulfur speciation (pyrite (FeS₂), iron monosulfide (FeS) elemental sulfur, and sulfate) and pH during oxidation of monosulfidic black ooze (MBO). (With permission after Burton, E.D., R.T. Bush, and L.A. Sullivan. 2006c. Acid-volatile sulfide oxidation in coastal floodplain drains: Iron-sulfur cycling and effects on water quality. Environ. Sci. Technol. 40:1217–1222. Copyright 2006c American Chemical Society.)

21.9. The oxidation of MBO follows a two-step process with oxygen consumption occurring with each step (after Burton et al., 2006c):

Step 1 FeS
$$\begin{cases} Fe^{2^{+}} + 0.5O_{2} + 1.5H_{2}O \rightarrow 2H^{+} + FeOOH \\ S^{2^{-}} + 0.5O_{2} + 2H^{+} \rightarrow H_{2}O + 0.125S_{8} \end{cases}$$
(21.10)

Step 2
$$0.125S_8 + 1.5O_2 + H_2O \rightarrow SO_4^{2-} + 2H^+$$
 (21.11)

The first step is a rapid chemical reaction of iron monosulfide minerals with oxygen, forming iron oxides and elemental sulfur. This initial oxygen-consuming step does not affect pH and is, therefore, nonacidifying. It is probably for this reason that the role of MBO in deoxygenation was overlooked until recently. Acidification associated with MBO oxidation can result from the second step, the microbially mediated oxidation of elemental sulfur, when oxygen is available (Figure 21.9).

Elevated elemental sulfur concentrations in deoxygenated waterways in acid sulfate soil landscapes may be a useful indicator of MBOs as a contributing cause to deoxygenation, although elemental sulfur can also form as a primary product of H₂S oxidation, and may be present within MBOs, prior to flood events (Burton et al., 2006a, 2006b).

21.5.5 Production of Noxious Gases

Anthropogenic and biogenic sulfur-containing gases have important impacts on global climate change (Charlson et al., 1987; Lohmann and Feichter, 2005), and atmospheric acid-base chemistry (Berresheim et al., 1995). Coastal estuarine and marine environments are major emitters of biogenic H₂S (Aneja, 1990; Bates et al., 1992). Emissions of H₂S, and more recently SO₂, from floodplains have been linked to acid sulfate soil management (Macdonald et al., 2004b).

H₂S is a highly noxious gas that causes distress to humans (Luther et al., 2003; EPA, 2003) and threatens aquatic organisms (Diaz and Rosenberg, 1995; Rabalais, 2002). As described by Equation 21.1, H₂S is produced by sulfur-reducing bacteria under anoxic conditions. Even at small concentrations, H2S can be detected by its characteristic rotten-egg odor. In acid sulfate soil landscapes, periodically inundated soil surfaces, shallow waterways, and field drains, where stratified anoxic conditions can develop, are all situations conducive to sulfate reduction and the formation of H2S (Dent, 1986). However, H2S is an unstable phase and its persistence in water and soil and ultimate gaseous emission is highly constrained by a wide range of oxidants in natural sediments and water bodies (Jorgensen et al., 1991). These oxidants include O2, NO3, Mn, and Fe oxyhydroxides (Froelich et al., 1979; Luther et al., 1997). Due to their abundance in acid sulfate soil, iron oxides (Millero et al., 1987) are a particularly effective oxidant of H₂S, a process leading to the formation of iron sulfides as described previously. Hydrogen sulfide becomes a problem when the rate of its formation exceeds the catalytic oxidative capacity of the sediments and water bodies to eliminate its gaseous emission. An excess of labile carbon and stagnant water bodies create conditions that favor H₂S emissions in acid sulfate soil landscapes (Rozan et al., 2002).

Partially oxidized RIS-containing acid sulfate soil materials are a known source of SO₂. Macdonald et al. (2004b) quantified SO₂ flux from agricultural acid sulfate soils using both ground chamber and micro metrological methods. In this study, the rates of SO₂ emission from the soil was closely linked to soil moisture and evaporative flux, leading the authors to conclude that acidic dissociation of sulfite (SO₃²⁻) occurring within the near-surface soil porewater was probably the major source of SO₂. The precise mechanisms for SO₂ formation in acid sulfate soil require resolution—bacterial processes that utilize sulfate (Saltzman and Cooper 1989) or organo-sulfur compounds (Freney, 1961) are both possibilities. From relatively few measurements, Macdonald et al. (2004b) estimated global SO₂ emissions from

acid sulfate soil to be 3.0 Tg S year $^{-1}$, \sim 3% of global anthropogenic emissions.

21.5.6 Scalding of Acid Sulfate Soil Landscapes

Scalded (i.e., nonvegetated) land surfaces can be an extreme symptom of land degradation and in low-lying acid sulfate soil landscapes can extend for hundreds of hectares, impacting both the environment and those who live and rely on these areas. Scalded acid sulfate soil land is environmentally damaging, agriculturally unproductive, and difficult to rehabilitate. There are a multitude of causes for the complete and prolonged failure of vegetation to establish. In acid sulfate soil landscapes, extreme acidification and/or salinization are often involved with the initiation of scalds (Rosicky et al., 2004a, 2004b). Peat fires arising from the desiccation of low-lying backswamps can also lead to the formation of scalds, as can the prolonged inundation of low-lying areas with acidic-aluminum-iron rich surface waters.

The size and condition of scalds vary considerably, spatially, and temporally. In a broad study of scalds along the east coast of Australia, Rosicky et al. (2004a) found that even relatively minor changes such as a shift to wetter conditions could instigate the rapid growth of acid tolerant plants such as spike-rush (*Eleocharis acuta*). The establishment of such revegetation typically would advance from the edge of scald, only to die off and recede when drier conditions returned.

Rosicky et al. (2004a, 2004b) found that the surface soil layers of scalds experienced extreme acidification (pH < 3), evaporative accumulation of acidic salts and metals (Al, Fe), high salinities caused by the accumulation of evaporative salts (e.g., gypsum), and accumulations of iron minerals (e.g., schwertmannite, ferrihydrite, goethite and jarosite). Combined with other stresses such as grazing pressure and frosts, such soil conditions generally prevented the long-term establishment of vegetation.

The primary goal for restoring scalds is to establish persistent vegetation. Strategies for revegetating scalds generally revolve around improving the surface soil layers by practical agricultural intervention. Techniques that have been demonstrated to work include the exclusion of stock, the use of ridges and furrows, mulching, liming, addition of fertilizer, pretreating seed with nutrients and neutralizing agents, and, more recently, water management practices that create and maintain wetter conditions. Of particular interest are the simpler interventions such as ridging and furrowing. This remediation involves the forming of ridges and furrows using cultivation, and especially when combined with a mulch layer (e.g., straw), it has proven very effective in facilitating the establishment of vegetation (e.g., Figure 21.5b). Ridges and furrows establish different microhabitats, with the water-tolerant species occupying the wetter furrows (Rosicky et al., 2006). A similar approach for food crop production on acid sulfate soils has been used by farmers in Southeast Asia for decades (Dent 1986).

More recently, landholders have begun experimenting with water table manipulation to provide more persistent wetter conditions to enable plant establishment on scalds. Excessive drainage is generally the most important primary driver of acid sulfate soil scald formation and strategies that reduce evaporation from bare areas and maintain or raise water tables in the near vicinity of scalds can contribute to their restoration and revegetation. The shallow ponding of fresh water can trigger rapid and complete revegetation of scalds (Rosicky et al., 2004b).

21.6 Physical Behavior

21.6.1 Consistence and Strength

Estuarine and marine sediments are usually deposited under saturated conditions. Many of these sediments contain up to 70% water and have a gel-like consistence. These extremely soft sediments pose significant challenges, due to their capacity to shrink on drying, deform under load, and oxidize and acidify when disturbed. The unique physical properties of sulfidic gellike soil materials have been well described (Dent, 1986). White (2002) has provided a very detailed analysis of the swelling and hydraulic properties of gel-like unoxidized sulfidic clayey acid sulfate soil materials. From their analysis, these soft sulfidic soils are fundamentally different to many rigid soils with both hydraulic conductivities and consolidation coefficients for the gel materials often being generally very low (e.g., hydraulic conductivities <1 m day⁻¹).

Drainage and oxidation of sulfidic soils usually results in irreversible shrinkage and development of fissures and structure. "Soil ripening" is a term used to embrace the physical, chemical, and biological processes that transform unconsolidated sediment to a structured, soil (Dent, 1986). The pedological development of unoxidized sulfidic acid sulfate soil materials to fully oxidized sulfuric materials has been summarized by Dent (1986). Acid sulfate soil profiles often consist of oxidized, sulfuric horizons overlying unoxidized, sulfidic horizons, with a transition zone of variable thickness inbetween. The overlying sulfuric horizon generally has far greater structural development than the underlying sulfidic horizon due to physical ripening processes.

At the time of deposition, clayey marine sediments can have an open "house-of-cards" microporous architecture with water-filled pore space. This type of clay microstructure confers minimal frictional and cohesive strength to the sediment. Even though on a microscale these materials are highly porous, hydraulic conductivities tend to be low due to the lack of connected macropore networks (Johnston et al., 2009). The removal of water by drainage, evaporation, and evapotranspiration causes the microstructure to collapse, increasing cohesive strength and initiating shrinkage-induced fissures. The development of such structure ultimately enhances the potential oxidation of iron sulfides and further microstructural collapse as a

result of acidic weathering. Unripe soils are soft, whereas ripe soils are firm and not overly "sticky" (Dent, 1986). The process of ripening is irreversible, and as a consequence, can cause land subsidence of up to 2 m, depending on the depth of previously unripe soil affected by oxidation.

21.6.2 Permeability

Lateral seepage of acidic ground waters is often the major route for the discharge of contaminants from acid sulfate soil to nearby waterways (Wilson et al., 1999; Åström, 2001; Johnston et al., 2003). The hydraulic gradient and hydraulic conductivity (permeability) govern the overall groundwater seepage rates. Factors that affect hydraulic gradient include rainfall, topography, and in coastal low-lying landscapes the water level at the discharge site. In an open estuary, this will be governed by tidal fluctuations. In a controlled drainage system, a designed water level may be set by one-way tidal gates or drainage pumps.

The hydraulic conductivity of acid sulfate soil materials varies greatly, both vertically within an acid sulfate soil profile and laterally across the landscape (White, 2002; Johnston et al., 2009). Ripening processes and spatially variable properties can induce considerable variability in soil structure and consequently, large differences in hydraulic conductivity in sulfuric horizons. The scale of the potential range in the hydraulic conductivity of acid sulfate soil landscapes was demonstrated in a recent study by Johnston et al. (2009) who examined seven coastal floodplains in eastern Australia. The

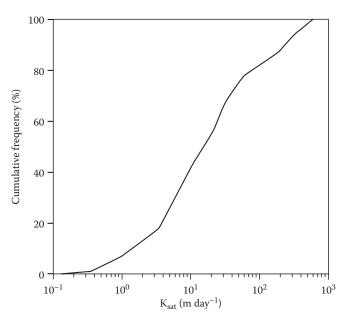

FIGURE 21.10 Cumulative frequency histogram of saturated hydraulic conductivity (K_{sat}) for 148 pits in acid sulfate soil landscapes in eastern Australia. (Modified from Johnston, S.G., P.G. Slavich, P. Hirst, R.T. Bush, and T. Aaso. 2009. Saturated hydraulic conductivity of sulfuric horizons in coastal floodplain acid sulfate soils: Variability and implications. Geoderma 151:387–394. Copyright 2009, with permission from Elsevier.)

measured saturated hydraulic conductivity (K_{sat}) ranged from <1 to >500 m day⁻¹ (Figure 21.10). These large differences in K_{sat} reflect differences in the development, orientation, and density of macropore networks, with the highest K_{sat} occurring in soils with large tubular macropore networks (Johnston et al., 2009).

21.7 Use, Management, and Evaluation of Acid Sulfate Soil Landscapes

21.7.1 Introduction

Management decisions have been taken, and are still being taken, without adequate knowledge of the unique characteristics of acid sulfate soils. Scientific assessment is often involved only after severe problems have arisen and the development of assessment methods has often focused on improvements in accuracy and precision of specific analytical determinations rather than dealing with soil heterogeneity and data interpretation.

Methods of reclamation and land use/management that have the single purpose of enabling and improving agricultural production may cause adverse environmental effects. In Australia, drained sugarcane fields have released acid into surface waters after heavy rains causing fish kills and ulcerative disease outbreaks in fish due to fungal infections (Callinan et al., 1993). On the Plain of Reeds in the Mekong delta, Minh et al. (1997) found that more Al³⁺ was leached into the surface water early in the rainy season from pineapples and yams (*Dioscorea alata*) in raised beds than rice fields. During a 4-month period, rice, yam, and pineapple fields released 2.2, 41, and 44kmol Al³⁺ ha⁻¹, respectively.

Existing methodology (Dent, 1992; Xuan, 1993; van Mensvoort, 1996) allows problems to be reliably diagnosed and on-site reclamation and precautionary water table management undertaken to avoid, or at least minimize, acid generation. Despite the severe acidity and associated toxicities of acid sulfate soils, a wide range of land uses is found on these soil types. For generations farmers in tropical coastal wetlands such as the Mekong delta of Vietnam (Xuan et al., 1982; Xuan, 1993; Tri, 1996) have, with great perseverance and skill and often at great cost, developed methods to coexist with the toxicities of acid sulfate soils. Soil and water management is the key to solving the problems of acid sulfate soils (van Breemen, 1976; Tuong, 1993). Surface and water table management, leaching, narrow drain spacing, maintenance of downward water flow, good leveling, timely plowing, and puddling are the most important measures to consider.

21.7.2 Land Use on Sulfidic Acid Sulfate Soils

21.7.2.1 Mangrove Forest Exploitation

Dramatic disappearance of mangrove (*Rhizophora spp.*) forests for charcoal production on sulfidic acid sulfate soils and replacement by shrimp farming has been reported from the Mekong delta (Durang, 1995), and is likely to have happened elsewhere as well. Besides removal, mangrove forests are commonly overfished, resulting in the disappearance of a large number of

aquatic species. Assessment of the severity of the acid sulfate hazard on other land uses may provide a powerful argument for retaining and protecting these natural ecosystems.

21.7.2.2 Fish or Shrimp Ponds

Brinkman and Singh (1982) developed a method of reclamation for fishponds on sulfidic acid sulfate soils in the Philippines. Using the salt water tides, they drained the ponds for forced oxidation of FeS₂, plowed the pond bottom to promote oxidation, allowed salt water to reenter to dissolve the acid formed, redrained the acid water at low tide, and repeated the process. After—three to five treatments, the pond bottom was free of acidity. Dikes were also washed with salt water. Rice and fish yields increased by 2.1 Mg ha⁻¹ and 400 kg ha⁻¹ year⁻¹, respectively, on reclaimed land (Ligue and Singh, 1988).

21.7.2.3 The Rice and Shrimp System

This system (Xuan et al., 1986) is applied on both sulfidic (where it was developed) and sulfuric acid sulfate soils in the Mekong delta. The monsoon climate with its contrasting dry and wet seasons allows farmers in coastal lands to exploit the fresh and saltwater periods for rice and shrimp production. Land located next to a creek or a canal with large tidal fluctuations is surrounded with a deep ditch and dike of excavated material. At the onset of the rainy season, the water is quickly drained to reduce the salinity so that the rice seedbed is ready early. Rice is sown or transplanted with reported yields of 4 Mg ha-1 of paddy. By that time the rains have stopped and surface water becomes saline, the fields are flooded with saltwater and kept submerged or almost submerged throughout the dry season. In the original version of the system, shrimp were caught from natural fry, resulting in yields up to 690 kg ha-1 year-1. Fresh sediment was deposited on the field annually from tidal water, raising the land and filling the ditch. This material—composed of good alluvial material without acidity—was used to raise the surrounding dike. Unfortunately, this system was undermined by its own success as too many people applied the system and exhausted the natural waters of fry. Because shrimp farming is economically more attractive, farmers abandoned the system and only cultivate shrimp using purchased fry. Because these shrimp are raised in the early rainy season, the farmers also abandoned rice cultivation. However, declining shrimp yields since 1994-1995 resulted in poverty for many.

21.7.2.4 Drainage

The aim of this technique (Xuan et al., 1982) is to accelerate salt removal during the early rainy season. Each field is provided with a surrounding shallow ditch and dike, plus a number of parallel field drains and a gate. At the start of the rainy season, farmers drain salt quickly from their fields at low tide, and close their gates at high tide. The system enables farmers to have two crops of short duration rice or rice combined with a short-duration upland crop such as watermelons or beans. Banjarese farm-

ers in southern Kalimantan apply a similar shallow drainage system called "handils" (Sarwani et al., 1993).

21.7.3 Land Use on Sulfuric Acid Sulfate Soils

21.7.3.1 Extensive Exploitation

This activity includes of harvesting reeds for matting, and exploitation of indigenous and planted *Melaleuca leucodendron* for timber, firewood, and oil extraction (Brinkman and Xuan, 1991), but few viable options are available on sulfuric acid sulfate soils with severe acidity at shallow depth.

21.7.3.2 Rice

Rice is by far the most important crop cultivated on acid sulfate soils. In the Mekong delta, soils with a sulfuric horizon deeper than 50 cm have been used for many years for traditional or deep water rice cultivation (yielding about 1 Mg ha-1). Until recently, inland freshwater sulfuric acid sulfate soils, where the sulfuric horizon is located near (<50 cm) the soil surface, were scarcely used for cultivation. After the economic reforms of 1986, settlers moved into these uncultivated lands with these soils. Coolegem (1996) estimated that from 1987 to 1995, 53% of the land in a district dominated by sulfuric acid sulfate soils had changed from wasteland or Melaleuca leucodendron forest to irrigated rice, during the dry season (28% of the entire district). Husson and Phung (1994) reported that relatively minor changes in elevation (a few centimeters) of fields in relation to the water levels in the growing season were responsible for significant differences in yields. Higher areas suffer from difficulties in maintaining adequate water depth to reduce oxidation and thus acidification, while the lower areas suffer from problems associated with reduction at depth (Fe2+ and H2S toxicities). Many elevation differences may occur within one field, causing great heterogeneity in crop growth. Hanhart et al. (1997) and Hanhart and Ni (1993) developed a set of water management measures for crops, such as rice, recommending good leveling, narrow drain spacing (30-60 m) to create a downward flow of water through the surface soil, and brief drying of the surface soil at flowering to avoid reduction at depth. Yields obtained were 3.6-3.8 Mg ha-1 with the economic breakeven point being 2.15 Mg ha⁻¹. Drainage from the rice fields carries an estimated 5 kmol H+ ha-1 crop-1 into the surface water, so irrigation and drainage waters should be kept separate. In areas with saline surface water in the dry season, traditional rice is cultivated. Moderate fertilizer levels of 100 kg N ha-1 and 60 kg P ha-1 are recommended, together with a small lime application to improve Ca2+ availability (Ren et al., 1993). Poor relationships between uptake and activity of Ca2+, Mg2+, and Fe2+ in the soil solution have been found for rice on acid sulfate soils, and Moore and Patrick (1993) recommend instead using the charge fraction of these ions in the soil solution, which show much better relationships with plant uptake.

21.7.3.3 Balanta System

In West Africa (Senegal, Guinea Bissau) farmers use the "Balanta" system for rice cultivation (van Gent and Ukkerman,

1993) in which land is ridged annually to a height in accordance with the expected freshwater flood of the rainy season. The ridging and annual turning of soil speed up removal of soluble toxins from the surface soil, but the system is in decline because of its heavy labor demand and low financial returns.

21.7.3.4 Annual Upland Crops

Yam, sweet potato, cassava, and sugarcane are the most important crops. These crops precede rice cultivation in places where no proper water supply for rice in the dry season is available. Farmers make raised beds by piling up the surface soil before the start of the rainy season. Beds are leached strongly during the wet season. Crops are planted immediately after the recession of the flood. Moisture is supplied by residual water from the soil, water in the ditches between the beds, and from capillary rise. For yam, vegetative growth is luxuriant, but yields are modest (~6 Mg ha⁻¹, compared to yields of 15 Mg ha⁻¹ on areas not requiring beds). The disappointing yields are attributed to excess moisture near harvest, when the rainy season starts again (Durang, 1995). After about 3–4 years, the land is leveled and, provided a source of irrigation water is available, rice is cultivated in a double crop system (Tri, 1996).

21.7.3.5 Perennial Upland Crops

Sugarcane, pineapple, and cashew nut, which all require well-drained soil in the flood season, are grown on beds raised well above the level of the flood. Sugarcane on acid sulfate soils suffers from poor tillering, short and thin canes, with total yields averaging ~50 Mg ha⁻¹ (Derevier, 1991) while yields on the other soils of the Mekong delta can reach 120 Mg ha⁻¹. Although Al³⁺ toxicity was suspected to be the cause of poor crop yields, no correlation between soil Al³⁺ and plant nutrient content could be established (Nga et al., 1993). For pineapple, fertilization and mulching with grass, a sufficient height above the flood is recommended (Sen et al., 1987; Tri, 1996) leading to yields of 40–50 Mg ha⁻¹, even in areas where irrigation is limited.

21.7.4 Integrated Soil, Water, and Crop Management

Tri (1996) presented an historical account of land use on the Mekong delta showing that the soil–water management measures (raised bed construction, plowing, puddling, leaching, construction of an irrigation and drainage system, field water management during the rice crop) that were taken as changes in land use were being made. This illustrates clearly how soil and water management are of primary importance for the proper management of acid sulfate soil landscapes. The assessments were mainly made by the farmers themselves, but the integration of different soil and water management practices can only be made by the community of land users. Land use has evolved through their learning processes. Significantly, the problems perceived first were those of drainage and water supply, and only later, water table management, in recognition of the acidity problems that subsequently developed.

21.7.5 Land Evaluation

Tuong et al. (1991) used hydrological factors to determine land quality in the Mekong delta for rice cultivation (double or triple cultivation, modern or traditional rice). The hydrological land qualities selected were (1) fresh water flood depth and flood duration during the wet season, (2) rainfall amount and distribution—emphasizing the occurrence of dry spells in the early rainy season, (3) tidal influence, (4) periods during which saline surface water is present in the dry season, and (5) the adequacy of canals for irrigation. For instance, flood depths of <30, <60, and >60 cm allow modern, short-duration, and traditional and deep water rice cultivation, respectively. Tidal influence is judged for its potential in irrigation without pumping; a long period under saline surface water may leave insufficient time for double-cropped rice too.

From a land evaluation study of the acid sulfate soil part of the Mekong delta that, in addition to assessment of hydrology, also included soil conditions and used a wider range of land use types, van Mensvoort et al. (1993) concluded that making fresh water available improves the suitability for rice on all acid sulfate land, and that well-constructed raised beds make moderately acid soils (sulfuric horizon >50 cm) highly suited for pineapple and sugarcane.

Using the same but more detailed methodology, Tri et al. (1993) evaluated two Mekong delta districts, one only partly hampered by acid sulfate soil problems, and the other dominated by sulfuric acid sulfate soils. On moderately acid land, land utilization types such as annual sugarcane in the dry season followed by rice in the wet season, cashew intercropped with pineapple, double rice cultivation and *Melaleuca* forestry, could be recommended. On sulfuric acid sulfate soils with much more difficult hydrological conditions, only single or double rice, or yam could be recommended.

The success or failure of the land utilization types depends, however, on farmers' skills. Present land use and farmer skills form, in fact, the basis for both land evaluation studies. In the studies of Tri (1996) and van Mensvoort (1996), acid sulfate soil knowledge at various levels (farmers, experts, and specialists) is brought together. All knowledge levels are valued equally, but farmer-level knowledge seems to have been underused in the past. Farmer-level knowledge is built on generations of experience in using the land and not only generated interesting land use systems (rice/shrimp, yam, sweet potatoes, pineapples, etc.) but also explained how these systems were historically developed, under what conditions or in what sequence these systems can be used, and what management measures need to be taken (e.g., leaching, mulching, no-till, raised bed construction). Expert-level knowledge such as fertilizer recommendations based on field experiments (Ren et al., 1993), refinement of water management measures (Tuong, 1993; Hanhart and Ni, 1993; Hanhart et al., 1997), and variety selection (Xuan, 1993) can be regarded as complementary, reinforcing the skills of farmers. Finally, true specialist knowledge of a more fundamental nature can also contribute to improved land use, for example, by better survey methods to improve land use planning (Burrough et al., 1988; Bregt et al., 1993), by developing a better grasp of soil–plant relationships through improved methods of chemical characterization (Moore and Patrick, 1993), or by modeling the processes in acid sulfate soils (Bronswijk and Groenenberg, 1993). A coherent and accessible decision support system has been produced by Dent and Dawson (1998) to help assist in this area.

21.8 Identification and Assessment

Accurate identification and assessment of acid sulfate soil materials is critical for acid sulfate soil management if the environmental hazards that these soil materials present are to be avoided or controlled. The basic accepted concept of a sulfuric soil material is one that is strongly acidic as a result of the oxidation of RIS. The concept of what constitutes a sulfidic soil material is, generally, that the soil material has the potential to become a sulfuric material following oxidation of the RIS it contains. However, precise uniform widely accepted definitions of "acid sulfate soil material," and of the related terms such as "sulfidic" and "sulfuric" soil materials, do not exist and in the case of the term "sulfidic," two distinctly different technical uses of this term exist, both within science in general and within soil science in particular, as will be discussed later.

21.8.1 Identification and Assessment of Sulfuric Material

Although essentially unified by a central concept, the definition of sulfuric soil (material or horizon) varies among soil taxonomies.

The definition for sulfuric soil material used in the Australian Soil Classification (Isbell, 1996) is as follows:

Soil material that has a pH less than 4 (1:1 by weight in water, or in a minimum of water to permit measurement) when measured in dry season conditions as a result of the oxidation of sulfidic materials (defined above). Evidence that low pH is caused by oxidation of sulfides is one of the following:

- Yellow mottles and coatings of jarosite (hue of 2.5Y or yellower and chroma of about 6 or more).
- Underlying sulfidic material.

For recognition as a Thionic (i.e., a sulfuric) horizon the World Reference Base (IUSS Working Group WRB, 2006) stipulates that the subsoil horizon that must have

- 1. pH < 3.5 in a 1:1 water suspension
- 2. a. either yellow/orange jarosite [KFe₃(SO₄)₂(OH)₆] or yellowish-brown schwertmannite [Fe₁₆O₁₆(SO₄)₃ (OH)₁₀·10H₂O] mottles
 - or—concentrations with a Munsell hue of 2.5Y or more and a chroma of 6 or more

or

b. superposition on sulfidic soil materials

- or
- c. 0.05% (by weight) or more water-soluble sulfate
- 3. Thickness of 15 cm or more

In the USDA Soil Taxonomy (Soil Survey Staff, 2010) the requirements for a sulfuric horizon is as below:

The sulfuric horizon is 15 cm or more thick and is composed of either mineral or organic soil material that has a pH value (1:1 by weight in water or in a minimum of water to permit measurement) of 3.5 or less or less than 4.0 if sulfide or other S-bearing minerals that produce sulfuric acid upon their oxidation are present. The horizon shows evidence that the low pH value is caused by sulfuric acid. The evidence is one or both of the following:

- 1. The horizon has:
 - Concentrations of jarosite, schwertmannite, or other iron and/or aluminum sulfates or hydroxysulfate minerals; or
 - b. 0.05% or more water-soluble sulfate; or
- The layer directly underlying the horizon consists of sulfidic materials (defined above).

All three example definitions of sulfuric horizon provided above have much in common, and the differences that do exist—except in the choice of the critical pH—are relatively minor. The critical pH chosen in the Australian Soil Classification (Isbell, 1996) definition of sulfuric is 4 whereas in the WRB (IUSS Working Group WRB, 2006) the critical pH is 3.5.

For assessment and management purposes, both of the following two different acidity-related measures of sulfuric soil materials usually need to be assessed:

- 1. pH. Determined either in water or dilute solutions, pH measures the "intensity" of the H⁺ and is a most useful measure of the geochemical environment.
- 2. Titratable Actual Activity (TAA). Determined usually by titration of a soil suspension up to a defined pH (usually 6.5), the TAA is a measure of the capacity of the soil material to supply acidity. In acid sulfate soil materials the main components of the TAA are Fe³⁺, Al³⁺, as well as H⁺ (Ahern et al., 2004).

21.8.2 Identification and Assessment of Sulfidic Material

As recently discussed in Sullivan et al. (2009a) there are several approaches that have been used for the identification and assessment of sulfidic soil materials.

21.8.2.1 Total Potential Acidity/Titratable (or Total) Actual Acidity

The total potential acidity/titratable (or total) actual acidity (TPA/TAA) method of Konsten et al. (1988) assesses the acidity already existing in the soil material (i.e., the TAA) and the acidity after complete oxidation of the sulfides present using hydrogen peroxide

(H₂O₂) (i.e., the TPA). The difference between the TPA and the TAA is termed the total sulfidic acidity (TSA) and is assumed to be a measure of the acidity that is generated by the oxidation of the various sulfide mineral fractions. TPA/TSA is now considered as only a semiquantitative and inexpensive method limited by inconsistent relationships between TPA and/or TSA, and pyritic sulfur (Andriesse, 1993; Clark et al., 1996); both the TPA and TSA are no longer effectively considered as suitable stand-alone measures in Australia for the recognition of acid sulfate soil materials (Ahern et al., 2004).

21.8.2.2 Reduced Inorganic Sulfur Determinations

Unlike the incubation methods, RIS determinations are considered to be quantitative (Andriesse, 1993). However, until recently determinations of RIS in soil materials have involved difficult methods that were not compatible with the conduct of soil surveys (Beghein et al., 1978; Andriesse, 1993). However, recent methods for the determination of RIS in acid sulfate soil materials such as the chromium reducible sulfur methods (Sullivan et al., 2000; Burton et al., 2008) have been developed that are simple, rapid, and inexpensive.

Importantly, the concept of sulfidic (as currently widely used in soil science) does not simply imply the presence of appreciable sulfides, but rather that there is a surplus of sulfides in that material (cf. acid neutralizing capacity), such that when oxidized, the soil material is capable of becoming extremely acidic. (Distinctions between the uses of the term *sulfidic* in science will be addressed later.) Thus, soil materials containing even high sulfide mineral contents cannot be classified as sulfidic in many soil taxonomies, if there are sufficient neutralizing materials also present in the soil materials to prevent acidification.

21.8.2.3 Acid-Base Accounting

The long period of time usually required to gain results from the incubation method (i.e., at least several weeks) along with the need for quantitative analyses for calculating liming rates, has resulted in the development of an acid-base accounting (ABA) approach (Ahern et al., 2004). The ABA approach has gained widespread use for acid sulfate soil management. One of the benefits of ABA is that it is quantitative and provides data on the acidification hazard that are suitable for purposes such as acidity hazard prioritization, determination of liming requirements prior to oxidation, verification of liming quantities posttreatment, etc.

While many ABA approaches have been used for acid sulfate soil assessment, they all share a common underlying principle whereby the acidity hazard is the difference between alkalinity and acidity sources as shown below.

There are several sources of acidity and alkalinity in soil materials and in practice the determination of several of these acidity sources is determined and expressed separately in the ABA. A commonly used ABA for acid sulfate soils is the one given by Ahern et al. (2004) as shown below:

In this ABA, the existing acidity is defined as follows:

The Net Acidity in this ABA represents the acidity hazard of the soil material. The Potential Sulfidic Acidity refers to the potential for acidity to develop from oxidation of pyrite. The Potential Sulfidic Acidity is estimated from the RIS determination and assumes both the RIS to be pyritic sulfur and that the overall oxidation reaction occurs in completion according to Equation 21.9 [i.e., 1 mol of pyrite produces 4 mol of (H⁺) acidity].

The Existing Acidity comprises both Actual Acidity and Retained Acidity. Actual Acidity is a measure of the readily available soluble and exchangeable acidity in the soil material. Retained acidity is a measure of the more slowly available acidity contained within minerals such as jarosite and schwertmannite—the acidity in these minerals represents incomplete oxidation (cf. the equation above for pyrite oxidation). This acidity can be realized and released when these minerals decompose and this process can be a major source of acidity in drainage. For example, 1 mol of jarosite releases 3 mol of acidity as described by the following reaction:

$$KFe_3(SO_4)_2(OH)_6 \rightarrow 3FeOOH + 2SO_4^{2-} + 3H^+ + K^+$$
 (21.15)

The Acid Neutralizing Capacity (ANC) refers to the effective neutralizing sources. In acid sulfate soils acceptable sources of ANC include calcium and magnesium carbonates, exchangeable alkalinity, and organic matter; but sources of buffering that do not act above pH 6.5 are usually considered ineffective (Ahern et al., 2004).

In Australia, the minimum critical Net Acidity levels that initiate the development of detailed management plans, should acid sulfate soil materials be disturbed, vary according to soil texture and the amount of soil disturbed. For sandy soil materials, and/or where large amounts of soil materials are to be disturbed, the critical Net Acidity level is >0.03% S (or alternatively >18 mol (H⁺) Mg⁻¹ when expressed as acidity) (Ahern et al., 2004).

Limitations of the current ABA methods stem from both our incomplete understanding of the acidifying and neutralizing processes that take place in these soil materials and the lack of reliable methods to quantify Retained Acidity and Acid Neutralizing Capacity. These limitations include the following:

- It is not clear what proportion of the potential acidity capable of being produced by pyrite oxidation eventually becomes expressed. Similarly, our understanding of the kinetics of acidification and neutralization processes is limited.
- 2. The currently available methods for quantifying ANC in acid sulfate soil materials require improvement to provide

accurate determinations (Ahern et al., 2004). Current methods may either overestimate or underestimate the "real" ANC due to a number of reasons, including the following:

- a. Overestimation may be due to the inclusion of finely ground shell materials in the test sample derived from large shell materials in the field samples. Large shell materials are generally ineffective as a neutralizing agent but if finely ground, such components will be included in the ANC determination inflating the true capacity of the original field samples (Ahern et al., 2004).
- b. Overestimation of the ANC may also result from the imposition of extremely low pHs (e.g., pH < 2) when using acid back-titration methods (Ahern et al., 2004) and, hence, the inclusion of acid neutralizing mechanisms such as clay mineral dissolution that may not occur in natural acid sulfate soil environments with less extreme pHs.</p>
- The current lack of reliable quantification procedures for Retained Acidity can lead to inaccurate estimation of the acidity hazard posed by acid sulfate soil materials.

Despite these limitations, the quantitative capability of the ABA method provides distinct advantages for the purposes of managing acid sulfate soil materials over the other acid sulfate soil identification methods used for soil taxonomic purposes.

The WRB (IUSS Working Group WRB, 2006) also uses an ABA approach to identify sulfidic soil materials. The WRB defines sulfidic materials as having:

- 1. 0.75% or more S (dry mass) and less than three times as much calcium carbonate equivalent as S; and
- 2. pH (1:1 in water) of 4.0 or more.

Unfortunately, the widely distributed gypsic soil materials (i.e., soils materials containing appreciable gypsum (CaSO₄·2H₂O)) are often falsely identified as being sulfidic using the WRB approach, as total sulfur—rather than RIS—is used for identification.

21.8.2.4 Incubation Methods

This approach simulates natural acidification behavior and has been long used for the assessment of these materials. This method is considered to be direct, allowing the soil to "speak for itself" (Dent, 1986) with respect to whether or not the soil material will acidify upon oxidation. However, incubation can also be a protracted method requiring months to give a determination (Andriesse, 1993).

In this method, the incubating soil materials are kept at room temperature and at field wetness by rewetting as required. Critical pH targets and the required duration of the incubation period necessary to identify a soil material as being sulfidic have been widely discussed (Andriesse, 1993) and range from 3.5 to 4.0. The duration of incubation has ranged from a few weeks to over a year.

In the latest soil classification, systems using the incubation method for the recognition of sulfidic materials, both the critical pH target and the duration of incubation have been standardized. For example, the definition used in the Australian Soil Classification (Isbell, 1996) for sulfidic materials is as below:

A subsoil, waterlogged, mineral or organic material that contains oxidizable sulfur compounds, usually iron disulphide (e.g., pyrite, FeS₂), that has a field pH of 4 or more but which will become extremely acid when drained. Sulfidic material is identified by a drop in pH by at least 0.5 unit to 4 or less (1:1 by weight in water, or in a minimum of water to permit measurement) when a 10 mm thick layer is incubated at field capacity for 8 weeks.

As discussed by Sullivan et al. (2009a), this definition is similar but not identical to that used for sulfidic soil materials currently used in the USDA Soil Taxonomy (Soil Survey Staff, 2003).

Some problems have emerged regarding the duration of incubation being limited to 8 weeks in these definitions. For example, the results of Ward et al. (2004) indicated that 8 weeks of incubation only allowed minor oxidation of the RIS in some gel-like clayey pyritic soil materials. To overcome these issues and to allow "the soil to speak without being interrupted in mid-sentence" Sullivan et al. (2009a) used 2 mm thick incubation slabs to hasten acidification process and proposed changing the recommended duration of incubation (a) until the soil pH changes by at least 0.5 pH unit to below 4, or (b) until a stable pH is reached after at least 8 weeks of incubation. This new definition has been incorporated into recent protocols for recognition of sulfidic soil materials in Australia (e.g., Fitzpatrick et al., 2009; MDBA, 2010; EPHC & NRMMC, 2010).

21.8.2.5 Developments in Classification of Sulfidic and Monosulfidic Materials

As mentioned previously, the distinguishing feature of acid sulfate soil materials has been either the presence of RIS sufficient to cause severe acidification, or severe acidity as a result of the oxidation of those sulfide minerals (Pons, 1973; van Breemen, 1973). More recently, environmental hazards arising from sulfide-containing materials in soils and sediments additional to acidification have been recognized and include deoxygenation, metal and metalloid release, enhanced nutrient release, and release of gases, as described previously. Some of these additional environmental hazards are the result of sulfide-related processes that are redox-driven and not directly associated with acidification. Similarly, deoxygenation of waterways by mobilization of monosulfidic soil materials does not require, nor does it necessarily lead to, acidification (Sullivan et al., 2002; Burton et al., 2006c).

The recognition of the occurrence and importance of monosulfides in soil materials led to the inclusion of monosulfidic materials as a distinguishing property within mapping units of the Australian Atlas of Acid Sulfate Soils (Fitzpatrick et al., 2008). The Australian Atlas of Acid Sulfate Soils is a web-based hazard assessment tool with a nationally consistent legend, which provides information about the distribution and properties of both coastal and inland acid sulfate soil across Australia (Fitzpatrick et al., 2008).

Although severe acidification is a major environmental hazard that can arise from the disturbance or mismanagement of sulfide-affected soil materials, much recent literature on the behavior of sulfide-containing soil materials indicates (1) acidification is not the only important environmental hazard arising from these soil materials, and (2) soil classification systems for acid sulfate soil materials should be modified to accommodate sulfide-containing soil materials that do not have the capacity to acidify, but have the capacity to pose other sulfide-related environmental hazards.

The way that soil classification has used the term "sulfidic" has also proved to be problematic in terms of communicating effectively with the broader scientific community. When describing soil, sediment, rocks and water, scientists in related disciplines (e.g., ecology, geology, geochemistry, and zoology) use the term "sulfidic" differently from the way that soil classification systems have used it. For example, Sullivan et al. (2009b) conducted a literature survey of the 20 scientific papers that appeared first in the literature search results when the term "sulfidic" was associated with each of the terms "soil," "rock," "sediment," and "water." It was clear that when scientists in disciplines related to soil science use the term "sulfidic" to describe their media, they use essentially the plain English meaning of sulfidic (i.e., materials that contain sulfides). In contrast, when soil scientists used the term "sulfidic" in association soil, the soil materials not only contained sulfides, they also had to be capable of becoming strongly acidic (e.g., pH < 4) upon oxidation. As a result, in soil classification, seemingly alone, we cannot describe all sulfide-containing soil materials as being "sulfidic" materials. Identifying soil materials that can severely acidify as a result of sulfide oxidation is clearly a useful concept. However the term "sulfidic" for this concept as currently used in several soil taxonomies (e.g., Isbell, 1996; Soil Survey Staff, 2003; IUSS Working Group WRB, 2006) has been misleading to the broader scientific community who almost uniformly use sulfidic to denote "containing sulfides" (Sullivan et al., 2009b).

A new classification system (Sullivan et al., 2009b, 2010) for sulfide-affected soils has been adopted for use in Australia (e.g., Fitzpatrick et al., 2008, 2009; MDBA, 2010; EPHC & NRMMC, 2010) to accommodate the important group of sulfide-containing soil materials that do not severely acidify upon oxidation and are classified as being "nonsulfidic" by the main soil taxonomies, as well as monosulfidic soil materials.

This new classification system for acid sulfate soil materials (Sullivan et al., 2010) is as below:

Sulfidic

Concept: Soil material containing detectable inorganic sulfides.

Definition: Soil material containing ≥0.01% inorganic sulfidic S.

Hypersulfidic

Concept: Sulfidic soil material that is capable of severe acidification as a result of oxidation of contained sulfides. (Note: hypersulfidic soil materials are conceptually the same soil materials defined previously in soil classifications as "sulfidic")

Definition: (adapted from Isbell (1996) with modifications to inter alia account for recent improvements to the incubation method (Sullivan et al., 2009a):

Hypersulfidic material is a sulfidic material that has a field pH of 4 or more and is identified by experiencing a substantial* drop in pH to 4 or less (1:1 by weight in water, or in a minimum of water to permit measurement) when a $2-10 \, \mathrm{mm}$ thick layer is incubated aerobically at field capacity. The duration of the incubation is either: a) until the soil pH changes by at least 0.5 pH unit to below 4, or b) until a stable** pH is reached after at least 8 weeks of incubation. *A substantial drop in pH arising from incubation is regarded as an overall decrease of at least 0.5 pH unit.

**A stable pH is assumed to have been reached after at least 8 weeks of incubation when either the decrease in pH is < 0.1 pH unit over at least a 14 day period, or the pH begins to increase.

Hyposulfidic

Concept: Sulfidic soil material that is not capable of severe acidification as a result of oxidation of contained sulfides.

Definition: (Adapted from Isbell (1996) with modifications to inter alia account for recent improvements to the incubation method (Sullivan et al., 2009a):

Hyposulfidic material is a sulfidic material that (i) has a field pH of 4 or more and (ii) does not experience a substantial* drop in pH to 4 or less (1:1 by weight in water, or in a minimum of water to permit measurement) when a 2–10 mm thick layer is incubated aerobically at field capacity. The duration of the incubation is until a stable** pH is reached after at least 8 weeks of incubation.

*A substantial drop in pH arising from incubation is regarded as an overall decrease of at least 0.5 pH unit.

**A stable pH is assumed to have been reached after at least 8 weeks of incubation when either the decrease in pH is <0.1 pH unit over at least a 14 day period, or the pH begins to increase.

Monosulfidic

Concept: Soil material containing detectable monosulfides.

Definition: Soil material containing ≥0.01% acid volatile sulfidic S.

21.8.2.6 Sequential Extraction Methods

The oxidative dissolution of pyrite that occurs when acid sulfate soil materials are disturbed results in the release of metals previously associated with pyrite (van Breemen, 1973). The rate at which these metals are released into the labile fractions is dependent upon the geochemical regime (e.g., pH, redox potential, soil solution composition), as described previously. Sequential extraction procedures are a common method of assessing metal mobility in different operational fractions within soils and sediments. When used within their well-documented limitations (Rao et al., 2008), sequential extraction procedures can provide useful assessments of

changes in metal mobility, and in the case of acid sulfate soil, assessing the potential metal hazard that the unoxidized acid sulfate soil materials pose. Sequential extraction methods have been utilized in a comparative fashion to examine metal mobilization in acid sulfate soils. Both Åström (1998) and Sohlenius and Öborn (2004) compared metal mobility in different fractionations in the oxidized and unoxidized zones of in situ acid sulfate soil profiles. These studies showed that a range of metals were mobilized from the oxidized zones of acid sulfate soils, especially from the pyritic and residual soil metal fractions. More recently, a sequential extraction method featuring the separate partitioning of metals in the pyritic fraction has been specifically designed for acid sulfate soils (Claff et al., 2010).

21.9 Conclusions

Acid sulfate soils can greatly affect the environment of and societies within landscapes that contain these materials. A wide range of environmental hazards are presented by these soil materials. These include (1) severe acidification of soil and drainage waters (below pH 4 and often <ph 3); (2) mobilization of many metals (e.g., iron, aluminum, copper, cobalt, zinc), metalloids (e.g., arsenic), nutrients (e.g., phosphate), and rare earth elements; (3) deoxygenation of water bodies; (4) production of noxious gases (e.g., H₂S); and (5) scalding (i.e., denudation) of landscapes. Some of these hazards are caused directly or indirectly by the severe acidification, whereas others are not.

These environmental hazards can impact on infrastructure such as bridges, drains, pipes, and roadways. Waters draining from acid sulfate soil materials may be enriched in a wide range of potential toxicants, including metals and metalloids, endangering aquatic life and public health. Crops, trees, and pastures may all be severely affected by acid sulfate soil materials, as can aquaculture. The extent, location, properties, and the often intense demands made on acid sulfate soils for water and food supply dictate that the development of our understanding of these soils will need to continue apace. Certainly, the identification, assessment, classification, and management of acid sulfate soils will continue to present a wide range of challenges for soil science.

22.1 Introduction

Research Institute for Geo-Hydrological Protection

Lorenzo Borselli Universitad Autonoma

Dino Torri

Soil erosion refers to a series of processes leading to soil depletion *in situ* and the export of sediment toward downstream areas. This chapter will try to identify the main processes and their interrelationship with soil and soil properties. Some extremely important factors in the definition of soil behavior, such as vegetation, land use and wildfire, land leveling, and tillage erosion will be briefly discussed. The focus of this chapter is on processes of soil erosion rather than soil erosion models, each of which would require a chapter to itself. Our objective here is to review current scientific understanding of the processes that are important from the standpoint of soil science and soil observation, rather than the sum of their parts as described by a model.

22.2 Erosion Processes

Soil erosion by water takes place through three main processes: (1) wetting and detachment of soil particles, aggregates, clods, and large soil volumes from the soil mass; (2) movement of detached material (e.g., by gravity or by overland flow); and (3) deposition. Processes are also subdivided based on other criteria into (1) diffuse surface erosion (e.g., splash and interrill erosion), (2) linear erosion (rill and gully), (3) subsurface erosion (piping), and (4) shallow mass movements. Furthermore, the translocation of soil with machinery (tillage, land leveling, crop harvesting) or export of soil when harvesting root or tuber crops locally produces net soil loss or soil accumulation and, generally, a diffuse degradation of soil properties with increase of soil susceptibility to water erosion. In the following discussion, primary soil particles and aggregates (usually <5 mm) will be often grouped together under the term "grains."

22.2.1 Wetting of the Soil

As drops impact, detach, and compact the soil surface, the water content of soil changes. Soil wetting diminishes matrix forces because the capillary component disappears as water content increases. The van der Waals forces binding soil particles (especially clay particles, Frydman and Baker, 2009) decrease in intensity as interparticle distance increases due to water uptake. At the same time, chemical processes take place due to the interplay between soil particles, water, and ions. This can cause soil particle dispersion. Dispersion, which can vary in intensity, is always active (Borselli et al., 2001). It takes place at the soil surface mainly because infiltration and runoff water are usually low in ions (high ion concentration tends to enhance flocculation). Dispersion favors processes of pore clogging, which decrease water infiltration and enhance overland flow production. Ignoring dispersion has led to incorrect conclusions, usually in the nature of lower runoff intensities, lower erodibilities, longer time to ponding and time to runoff (Shainberg and Levy, 1996; Borselli et al., 2001). Values of these characteristics obtained using rainfall simulation made with low-quality water (e.g., tap water) should not be used for field application without correction.

Slaking of aggregates occurs during the first stages of soil wetting. This is due to the air trapped in the aggregates and compressed by the water driven into the soil by the matrix forces. The velocity of air diffusion through water (particularly in micropores) is lower than that at which water penetrates into the aggregates. This causes localized high pressure that can break interparticle bonds. The process is extremely rapid; a submerged dry clod can disintegrate in several minutes. Obviously, it ends as the soil water content approaches saturation. Usually, slaking diminishes and becomes negligible within 15–30 min after rainfall starts. The presence of slaking explains why erosion is often

more intense when the soil is dry before rainfall. The processes involved in slaking have been discussed in detail by Rengasamy and Sumner (1997).

22.2.2 Drop Impact and Splash Erosion

Drop impact is responsible for much of the detached sediment, changes in surface morphology, and sealing. Drop impact forces depend on the drop mass and its impacting velocity. Falling drops accelerate until a maximum velocity value (V_F) is reached (Laws, 1941). Final fall velocity (m s⁻¹) varies with drop diameter (Φ , mm) approximately as follows:

$$V_F = 9.38 \tanh (0.44\Phi)$$
 (22.1)

When the drop hits the soil surface, it compresses the soil and removes particles and aggregates entrained by a crown of lateral droplets that are ejected laterally and upward (Engel, 1955), excavating a micro-crater. Grains are ejected around with an ejection angle (measured between the ejection trajectory and the soil surface) increasing with the depth of the water film that covers the soil surface (Mutchler, 1967). In the absence of any water film the angle seems to vary inversely to soil resistance (Al Durrah and Bradford, 1982). The presence of a water layer at the surface protects the soil as the layer absorbs part of the drop impact force (Palmer, 1963; Torri et al., 1987). When a drop hits soil grains on a sloping surface, the ejected grains are propelled further in the downslope than in the upslope direction. This causes a net downslope movement of grains. Locally, this causes depression to be filled by splashed sediments while protruding spots are eroded. Substantially, this process gives rise to two types of crust: those due to soil compaction by raindrop impact in the protruding areas (i.e., structural crusts), and the sedimentary crust where deposition prevails (Valentin and Bresson, 1992). Besides these crusts, drop impact is recognizable by the typical erosion forms it leaves on the soil surface, that is, splash pedestals. Splash pedestals are generated where an un-erodible element (rock fragment, plant residue) protects the underlying soil grains so that drop impact forces are dispersed. Hence, the spot is not eroded and slowly protrudes above the surrounding eroded zone.

In order to estimate the amount of splashed material, the forces produced by the impinging drops must be estimated. Many researchers studied drop impact on rigid surfaces (e.g., Engel, 1955) or modeled it (e.g., Harlow and Shannon, 1967). Nearing et al. (1987) measured impact forces on soil surfaces produced by impacting drops, $5-6\,\mathrm{mm}$ in diameter, falling from 14 m. Using 1 mm piezoelectric transducers, they measured pressure peaks of about $300-400\,\mathrm{kPa}$ located on a ring at about $2-2.3\,\mathrm{mm}$ from the impact centre. Elsewhere in the impact crater, pressure values were close to $40\,\mathrm{kPa}$.

Since Ellison's studies (Ellison, 1947), raindrop energy has been the winning surrogate of the force of impact for describing drop detachment. Kinnel (1990) in his studies showed that drop impact increases overland flow transport capacity, enhancing soil erosion.

22.2.2.1 Vegetation Interception

Splash erosion is greatly modified by vegetation. Vegetation intercepts raindrops and subdivides water into three compartments: (1) stored on leaves and branches (which will finally evaporate), (2) re-dripped drops from leaves and branches (water in excess of storage), and (3) concentrated toward the "centre" of the plant (trunk, stem) where it reaches the ground as a flow along the trunk-stem (stem flow). This partitioning causes a decrease in rain impact energy because storage and stem flow water are subtracted from impacting raindrops. Re-dripping is characterized by drops that are generally larger than usual (4 mm in diameter approx., smaller in the presence of intense wind; Brandt, 1989). The average falling height of a drop is generally lower than 4–7 m (which is typical of medium-size trees) and is often close to zero (under small bushes or grass). Hence, drop kinetic energy is usually lower than that of raindrops (final velocity is reached in less than 20 m of falling height even by the largest drops).

This aspect becomes particularly important when natural and seminatural vegetation stands or agroforestry fields are considered because they are usually composed of a mixture of many plant species, living one under the other, where re-dripped drops from trees are intercepted and then partly re-dripped by bushes, to be caught by moss or litter or hit the bare soil. This is true also for many new and traditional crops (e.g., Lott et al., 2000a, 2000b; Diemont et al., 2006). The speed at which new varieties are adopted (and created), and new techniques invented makes it challenging to determine empirically the ability of vegetation to reduce splash erosion and protect the soil. Hence, models that make use of vegetation structure, partitioning raindrops and recalculating drop impact energy have a big advantage over models where vegetation is parameterized in a substantially empirical way such as the Universal Soil Loss Equation (USLE) C-factor (Renards et al., 1997; see Gabriels et al., 2003, as an example of C-factor adaptation).

Models describing in detail the behavior of plants in partitioning rain water and in protecting the soil are few. That developed by De Ploey (1982, 1984) and Van Elewijck (1989), was partly implemented in the runoff-erosion models EUROSEM (Morgan et al., 1998) and LISEM (De Roo et al., 1996; Jetten et al., 2006). Other similar models were developed independently by Gash et al. (1995, 1999), Navar et al. (1999), Crockford and Richardson (2000) and van Dijk and Bruijnzeel (2001). Plants are described through a series of parameters. They include crop cover and mean height of fall of re-dripped drops. Plant water storage represents the amount of water that is trapped at the plant surface: it is proportional to leaf area per unit of soil surface, which is often expressed through the leaf area index (or LAI). The water that is intercepted can be directed toward the inner part of the plant: this depends on the angle at which branches or stems help to concentrate intercepted rain water toward the central part of the plant (plant basal area). This central part can be either permeable (e.g., Stipa tenacissima) or impermeable (any tree's plant base) to water: in the former case infiltration and water storage in the soil

increase, in the latter case some erosion may be encouraged by the concentration of clear water at the plant intersection with the soil surface (as is the case with maize).

Roots increase soil shear resistance (*T*) substantially, acting probably through their exudates, binding soil grains among themselves and to the roots, and through mechanical action. A series of papers have recently tackled the effect of roots on concentrated flow erosion rates (Gyssels et al., 2005; De Baets et al., 2007, 2008) proposing relationships between root density and erosion reduction.

22.2.3 Overland Flow

Water flow detaches and transports soil particles and aggregates. Hence, the main characteristics of overland flow (diffuse and concentrated) must be understood and correctly calculated if we want to understand erosion and which characteristics of soil and vegetation are relevant.

22.2.3.1 Flow Velocity

Flow is characterized by its unit discharge rate, q (m² s⁻¹); velocity, u (m s⁻¹); and depth, h (m). Darcy–Weisbach and Manning equations provide links between these variables:

$$q = hu \tag{22.2}$$

$$u = \frac{h^{\beta} s^{0.5}}{m}$$
 (22.3)

where for the Manning equation m is equal to the Manning friction coefficient, n, and $\beta = 2/3$, and for the Darcy–Weisbach equation $1/m = \sqrt{8g/f}$ (where f is the Darcy–Weisbach friction factor) and $\beta = 0.5$. The Darcy–Weisbach equation has the advantage that the friction factor is dimensionless, which is not true of the Manning equation where n is measured in $m^{1/3}$ s⁻¹.

If channels have a large depth-to-width ratio then depth must be substituted by the hydraulic radius (cross section occupied by the discharge divided by the wetted perimeter).

Friction factors have been studied in detail by many researchers, but the main problem is that they depend on water depth or some derived parameter such as the inundation ratio (h/D) where D is a characteristic of the bed grain size (e.g. the diameter corresponding to the median or some other percentile of the grain-size distribution). Lawrence (1997) applied this concept to the Darcy–Weisbach friction factor f, from sheet to river flow.

Smart et al. (2002) and Aberle and Smart (2003) found the following formula, which is based on data collected in fixed non-erodible beds

$$\sqrt{\frac{8}{f}} = 0.91 \frac{h}{RR}$$
 (22.4)

where RR is the standard deviation of channel bed elevations.

A more complex approach to *f* can be found in Gilley and Weltz (1995) where vegetation, litter, and moss play different roles in rill vs. interrill flows, and in rangeland vs. cropland.

A simple way of estimating Manning's *n* is the one proposed by Gilley and Finkner (1991):

$$n = \frac{0.172RR^{0.74}}{Re^{0.282}} \tag{22.5}$$

where

Re is the Reynolds number ($Re = hu/\eta$)

n is the kinematic viscosity of water ($m^2 s^{-1}$)

RR (mm) is a measure of soil surface random roughness (i.e., surface irregularity such as clods, which cannot be perceived as oriented in any preferential direction).

In this case, *RR* is obtained by calculating the standard deviation of soil elevations at the surface measured with sticks or laser-equipped profilemeters (Zobeck and Onstad, 1987) once form trends have been removed.

Equation 22.3 is valid for clear water flow when the interaction between the fluid in motion and the channel are negligible, that is, no erosion. When runoff interacts with the soil surface it becomes sediment laden. Hence, overland flow uses part of its energy to detach and transport grains. It uses another part to modify the soil surface (and change roughness). Moreover, fluid density and viscosity are affected by the presence of sediment and ions (Vanoni and Nomicos, 1960). The following are some of the empirical equations found by different authors to describe local experimental data better than Equation 22.3:

$$u = 0.097Q^{0.137} (22.6.1)$$

calculated using data from Abrahams and Parsons (1990), for interrill runoff;

$$u = 3.52Q^{0.294} (22.6.2)$$

for rill channels in erosion (Govers, 1992) in the absence of constraints such as rock fragments, or important bed forms;

$$u = 16Q^{0.28}S^{0.48} (22.6.3)$$

for an unerodible fiber-glass replica of a rill channel (our calculation from data by Foster et al., 1984);

$$u = 2.88 \left(\frac{Q}{w}\right)^{0.68} \tag{22.6.4}$$

for steep step-pool channels (Comiti et al., 2007); where u is the mean velocity in m s⁻¹, Q is flow discharge in m³ s⁻¹, and S is bed gradient.

In a field study Hessel et al. (2003) found that Manning's n increases with slope, which is a clear effect of the erosion

interaction with the eroding overland flow, in agreement with laboratory observations made by Gimenez and Govers (2001) who found that surface roughness increases with erosion. The data of Hessel et al. (2003), collected in eroding rills in the presence of some physical constraints limiting erosion potential, plot below but parallel to Equation 22.6.2.

As the four Equations 22.6 show, they are quite different depending on the conditions under which they were calculated. The only relationship where slope gradient is present is Equation 22.6.3, which was calculated on a fixed non-erodible channel bed. The other equations were determined in field conditions while erosion was taking place, demonstrating that slope and hydraulic roughness are not present (or scarcely important) when erosion occurs. Obviously there must be some other parameter playing a similar role if we want all the equations to merge into a more general one.

22.2.3.2 Flow Detachment, Transport, and Sedimentation

The forces resisting detachment are the grain weight, its angle of friction with surrounding grains, and the cohesive forces with which each grain sticks to the soil mass. Detachment operates by drag and lift forces, which are roughly proportional to the flow velocity squared.

Flow detachment occurs when forces produced by runoff (drag and lift) are able to remove grains (detachment phase). As soon as the grain is entrained runoff accelerates it toward a velocity approximating the local flow velocity. At the same time, gravity tends to bring the grain back to the soil surface until the grain is eventually deposited.

Detachment is due to raindrop impact (which is dominant in interrill erosion, with diffuse and shallow overland flow), and to the forces produced by runoff. The latter case is often modeled using equations that estimate runoff forces using fluid stream power (p) or fluid shear stress (τ_F) applied to the channel bed surface:

$$p = \rho g q \sin \gamma \tag{22.7}$$

and

$$\tau_F = \rho g h \sin \gamma \tag{22.8}$$

where

p is in W m⁻²

 γ is the gradient (rad) of the channel bed (often equal to the local slope gradient)

q = Q/w is unit discharge

 τ_F is fluid shear stress (Pa)

These equations are rough proxies of the real situation, which is characterized by a local time distribution of shear stresses, wildly oscillating around a mean value (Naden, 1987). Consequently, particle detachment occurs even if the average

value of the detaching forces is smaller than that of the bonding forces (Naden, 1987; Nearing, 1991). Soil grain bonding forces are similarly (but spatially) distributed around a mean value. Hence, a partial overlap of the two distributions is sufficient to guarantee that soil erosion will occur. Moreover, removing a grain has the effect of making other grains less protected and more easily erodible. As a consequence, while mean soil resistance is usually measured in kPa, the flow shear stress eroding it may be close to a few pascals (Torri et al., 1987).

The trajectories followed by entrained grains during transport and sedimentation can be quite complex; some grains are transported in contact with the soil surface, by rolling or sliding, others in suspension or by saltation. Consequently, sedimentation equations, such as Stokes', are poor approximations of reality.

The concept of flow transport capacity is a means for overcoming this problem. Transport capacity is defined as the amount of sediment that a given flow can transport over an infinite length when detachment and deposition rates are equal. Many (>10) equations have been proposed mainly for rivers and channels. Among these, we can refer to those proposed by Govers (1990), which were specifically developed for rill conditions. These equations are used in EUROSEM and LISEM (Morgan et al., 1998; De Roo and Jetten, 1999).

Once transport capacity (T_C) is known, net erosion rate due to overland flow scouring can be assessed as a transport deficit. In this case, the amount of soil that will be detached (D_f) in excess of what is deposited is given by the following:

$$D_f = \beta u_S (T_C - T_A) \tag{22.9}$$

where

 T_A is the present sediment load

 u_s is sedimentation velocity

 β is a coefficient of proportionality, which takes into account soil shear strength (τ_s , measured with a pocket torvane at saturation) as follows (Morgan et al., 1998):

$$\beta = 0.79e^{-0.85\tau_S} \tag{22.10}$$

When Equation 22.9 gives negative values, then sedimentation is dominant and $\beta = 1$ by definition.

Other, nevertheless similar, detachment equations were developed starting from different concepts (Foster et al., 1989; Woolhiser et al., 1990). Some detachment equations were compared by Zhu et al. (2001) who found that power relationships seem to explain measured data better.

The general picture is further complicated by the fact that the raindrop-detached soil is easily entrained by the flow because these particles are already detached. As a result, splashed particles compete with overland flow detachment because both add to T_A (of Equation 22.9) modifying D_C

As it has already been said, part of the drop kinetic energy is spent on impact with the overland flow. This causes an increase in turbulence, which is important in shallow flows, that is,

in interrill erosion. Kinnel (1990) developed a set of equations to take into account this increase in turbulence to which there corresponds an increase in transported material. He developed a set of equations containing instantaneous rain intensity, flow mean velocity, and a complex function depending on raindrop size distribution. Interrill is further affected by raindrop impact as shown by the Australian school (Yu and Rose, 1999; Yu, 2003; Asadi et al., 2007) During splash erosion the soil surface becomes armored by the coarser grain fraction, which slowly caps the soil surface.

Obviously, interrill flow is influenced by the presence of small obstacles because overland flow is usually thin. This causes the flow to divert, turn around obstacles and follow paths that do not go along the steepest mean interrill gradient. Findeling et al. (2003) proposed an algorithm describing how the hydraulics of sheet flow is influenced by mulch cover. They included a flow tortuosity and a gradient along the tortuous interrill flow path as a function of the fraction of the surface covered by mulch.

22.2.4 Concentrated Flow Erosion (Rills, Pipes, Gullies)

Overland flow tends to rapidly coalesce into rivulets whose paths are unstable and can quickly change due to instances of local deposition or erosion. They wind around small protuberances until they reach local micro-depressions where they merge with other rivulets forming well-defined flow patterns that can eventually develop into rills. This aspect has been dynamically modeled by Favis-Mortlock (1998) who produced a model (RILLGROW) able to generate natural rill patterns very similar to those observed (Favis Mortlock et al., 2000).

Rill erosion is often treated by using Equation 22.9, and balancing erosion and deposition within the rill bed with the erosion inflow from interrill areas.

Rills are cut into the soil when the flow is sufficiently erosive. Smerdon and Beasley (1961) found that critical flow shear stress (computed using Equation 22.8), at which incision begins, increases linearly with clay content. This trend was not confirmed by data collected by Torri et al. (1987), who found that critical shear velocity for rill excavation increases with soil shear strength measured with a torvane. Rauws and Govers (1988) found a linear relationship (passing through the measured data) between flow shear velocity and soil shear strength (at saturation), which defined the threshold shear velocity to be overcome for the rill to be excavated. A more recent review (Leonard and Richard, 2004), mainly basing its deductions on the abovementioned studies and data-sets, suggests a linear relationship between soil shear strength and critical flow shear stress.

When a linear incision becomes too deep or too wide to be easily removed by normal tillage operations, the channel changes from a rill to a gully. If the gully is removed shortly after its formation (which is common in cultivated fields), then it is called ephemeral. For a closer definition of gully formation, independent of tillage equipment, any channel with ephemeral runoff and maximum cross-sectional area equal to or above 0.0929 m²

may be considered to be a gully (Hauge, 1977; Poesen et al., 2003). These definitions do not give differences between rills and gullies apart from the difference in size. While rills form on slopes, gullies usually form in thalwegs and the wall dynamics is important (mass movements and rills). Given their larger size, gullies usually drain larger catchments than rills. Hence, runoff is greater and lasts longer. Gully channels include both the incisions disappearing gradually upslope and those ending abruptly with a step. A classification of channel heads was proposed by Dietrich and Dunne (1993) on the basis of the morphology of the head: (1) gradual through small steps (<0.1 m), (2) large steps (0.1–1 m), (3) small headcuts (1–10 m), and (4) large headcuts (>10 m). Gullies have been classified in several ways, following genetic or morphologic criteria. They can be described as digitated if they repeatedly bifurcate while retreating until no dominant channel is clearly visible; axial when there is a main channel; or frontal, if the width of the retreating head is evidently larger than the length of the gully (Morgan, 1995).

Gullies are generated by concentrated overland flow sufficiently erosive to excavate deep or large channels that generally occur where several concentrated flow lines merge or where a concentrated flow of relatively clear water (e.g., an outflow from a forest, pasture or paved road) intersects a cultivated field. Furthermore, gullies may form because of local base-level lowering due to human activities or river dynamics. Even sea level lowering can trigger gully formation (Leyland and Darby, 2009). A retreating gully head can intercept un-eroded flow paths and cause tributary gullies to form. More generally, gullies may develop where the flow path intersects an earth bank, such as road or terrace banks, lynchets, etc. (Poesen, 1993). In addition, gullies form easily in highly dispersible soils or when pipes and tunnels collapse after reaching a critical size. This frequently occurs in sodic soils (Sumner et al., 1997).

Gully erosion has been documented as being responsible for 10%–94% of soil erosion (Poesen et al., 2003). Hence, it is of paramount importance to understand the process.

Gully erosion is characterized by an upslope retreat of the gully head. Gully sidewalls are usually reshaped by rills, slumps, and mud flows. The large quantities of sediment produced at the heads, walls, and over the bed tend to rapidly fill the transport capacity of the gully, reducing further bed scouring downstream. Hence, gullies are often characterized by an upstream segment where erosion is active and a downstream portion where sedimentation prevails. Where gully walls are made of easily weathered materials, early pedogenetic processes allow the development of alterites and entisols. Contact between the weathered and relatively unweathered layers makes for a discontinuous surface where permeability decreases abruptly, favoring soil saturation by water. As soon as soil formation reaches a certain depth that depends on local slope and soil shear strength values, new mass movements rejuvenate the gully walls. This process is typical of *calanchi*, ravines, arroyos. The deep incision of permanent gullies can trigger seepage erosion anywhere along its length. This, in turn, can cause the formation of new tributary gullies. If tributaries of different orders are numerous, they can intercept one another (with "valley" capture). In this case, residual surfaces of the original slope are confined between interconnected gullies (Bryan and Jones, 1997).

Topics of major interest for gully erosion are whether and where gullies form in a given landscape, how fast they will erode, and how far upslope they can retreat. Their location in the landscape is determined by local precipitation (drier areas require larger catchments than wetter ones), runoff contributing area, mean valley gradient, and local gradient at gully head. Montgomery and Dietrich (1994) showed that a threshold exists for channel head location, which depends on the area (A) of the drainage basin and the gradient (S) at gully head. Several sets of observations conducted in different geographic areas are discussed by Poesen et al. (1998, 2003). The general relationship expressing the threshold is as follows:

$$S \ge aA^{-b} \tag{22.11}$$

where

S is the local slope (m m⁻¹) A (ha) is the catchment area at the gully head $a \in [0.07; 0.11]$ in cropland, $a \approx 0.2$ in rangeland (Poesen et al., 1998)

 $b \in [0.1; 0.8]$ often being lower than 0.3

Recent data by Parkner at al. (2006) suggest smaller a and larger b values for pastures in the Waiapu catchment, New Zealand. Poesen et al. (2002) suggested a similar topographic threshold for rill initiation with and a = 0.0027 and b = 0.59.

Land use and soil erodibility play an important role in defining the threshold area. Retreat rates of gully heads depend on the amount of water that the gully head drains, that is to say, that gully heads retreat at a rate proportional to the catchment area (A). Seginer (1966) found the following relationship for gully retreat rate (G_R) in Southern Israel:

$$G_{\scriptscriptstyle R} = cA^{\xi} \tag{22.12}$$

The empirical constant c depends on local characteristics (soil, land use, topography, precipitation) while the value of the exponent ξ is generally close to 0.5. Stocking (1981) reported more complex relationships for Southern Africa.

A second threshold can be expected to exist in relation to where gullies end, due to the great amount of sedimentation that counteracts gully development (Poesen et al., 1998, 2002). Generally, whatever can cause a sudden increase in sedimentation can trigger an end to gully entrenchment. Hence, a change from arable to pasture or rangeland may cause a gully to end. More generally, this process can occur with any passage from a lesser to a more protective land use (Beuselinck et al., 2000). A decrease of slope gradient often corresponds to a decrease of runoff detachment and transport, which causes a decrease in gully channel depth and, eventually, the end of the gully. Attempts to define relationships like (22.11) have produced a set of data usually plotting somewhat below the corresponding data for gully initiation (Poesen et al., 2002). In cropland

areas of Northern Europe, ephemeral gully processes are usually dominated by sedimentation at a local slope gradient equal to or smaller than 0.02–0.04 in cropland. If rock fragment content is relatively large, then intense deposition may occur at gradients as large as 0.25–0.30 m m⁻¹ (Poesen et al., 2002).

More complex relationships have been proposed by others: for example, De Santisteban et al. (2005) developed two more elaborated topographic indices to characterize the influence of watershed topography on gully erosion, obtaining reasonable agreement between observation and prediction.

Usually, local equilibrium is established between the erosion processes that make sidewalls retreat and those that further scour the gully bed. Hence, local relationships between the width, depth and cross section of gullies can be established. For example, in the United States gullies are characterized by a width to depth ratio close to 3 on cohesive material and 1.75 in non-cohesive sediments (Reid and Dunne, 1996). Poesen et al. (1998) showed that the depth of an ephemeral gully increases rapidly beyond a critical slope (>3%–4%) unless an erosion-resistant horizon (e.g., Bt, plough pan, fragipan, etc.) is present at shallow depth in the profile.

Other processes, typical of linear incision, have been tackled in studies presented in a still on-going series of conferences on gully erosion, which was started in 2000 (Poesen and Valentin, 2003). Some of the major processes for gully erosion are still active fields of research (e.g., Prasad and Römkens, 2003; Torri and Borselli, 2003). Among gully models that stand out are those developed by Sidorchuk (1999), Alonso et al. (2002), and Casali et al. (2003). Processes include knick point evolution and head-cut retreat (Robinson et al., 2000). Øygarden (2003) observed all the aforementioned processes at work in various rills and gullies that developed during snowmelt in agricultural fields in Norway.

As already pointed out, there are discrepancies between theory and field observations. Govers et al. (2007) summarized some of them (we have already reported those regarding flow velocity, Equations 22.6) in the form of a set of equations, which constitute the rill-equivalent of the hydraulic geometry equations used in rivers (i.e., power equations). Nachtergaele et al. (2002) showed that rills and gullies may be characterized by an equation relating channel width (w) with the channel formative runoff discharge (Q). Torri et al. (2006) and Salvador et al. (2009) developed a channel width—discharge relationship and evaluated it in over more than 1500 cross sections of rills and gullies in badlands, rangeland, cropland and mountain forests located in Italy, Spain, Belgium, and Canada. Based on these studies, they expanded the relationship into the following:

$$w = \chi \left(\frac{Q}{Q_0}\right)^{\alpha} \tag{22.13}$$

where the parameters Q_0 has the dimension of a discharge and χ of a length, while the exponent α varies with channel width

$$\alpha = 0.534(1 - 0.354e^{-0.0255\overline{w}}) \tag{22.14}$$

 χ can be calculated using the junction method proposed by Torri et al. (2006) (see below) or deduced from tables (Salvador et al., 2009). Reliable methods or equations for the denominator Q_0 have not yet been developed (Salvador et al., 2009).

22.2.5 Pipe Erosion and Dispersive Soil Behavior

Pipes develop in particular situations. Some are linked to karstic processes, involving soil chemical dissolution and removal by subsurface flow, while others are linked to excess subsurface water that drains through cracks or macropores in which the water can flow fast enough to transport sediment. Subsoil sodicity further promotes clay dispersion and transport. These processes result in a pipe or a karst-like depression. The formation of pipes is facilitated by the presence of cracks or of impervious layers. If a soil horizon overlaying a less permeable layer has adequate horizontal hydraulic conductivity, water flows rapidly and becomes erosive. In other words, everything that promotes rapid accumulation of water beneath the soil surface (e.g., tectonic joints, micro-faults, cracks, biological macropores, etc.) or rapid water exfiltration (e.g., artificial and natural trenches such as gullies, landslides, abrupt increase of hill-slope gradient, etc.) promotes tunnel scouring and seepage erosion. Tunnel scouring takes place when subsurface water flows sufficiently fast to entrain soil particles.

Seepage erosion takes place when the water head can be dissipated at a scarp or at any other discontinuity, detaching particles and causing the discontinuity to retreat. An overview of pipe erosion was presented by Jones and Bryan (1997) depicting the various situations in which pipes can develop and their significance.

When soil dispersion occurs, seepage and piping can significantly modify processes and rates (Stocking, 1981) because dispersivity increases soil erodibility (Fitzpatrick et al., 1995). Faulkner et al. (2004) observed that peaks of sodium absorption ratio (SAR) correspond to zones of maximum incision (in Mocatan, Almeria, Spain). They also found that SAR increases with clay content. A well swelled clay can reduce, even suppress, infiltration. In this case water cannot penetrate any further and must move laterally, causing the formation of pipes subparallel to soil surface. Sometimes pipes are located under calcium-rich crusts. This local enrichment in calcium is due to the replacement of sodium during leaching. The description by Faulkner et al. (2004) is consistent with the observation that bed incision in pipes and rills in biancana badlands (Italy) is limited by the water front penetration velocity in the soil: only when saturated or near to saturation the material loses its high shear resistance and reaches soil shear strength values often below 0.2 kPa (Torri et al., 1994). Under these conditions, the presence of vegetation (pioneering species, such as Artemisia cretacea), the roots of which cause the formation of large connected porosity, accelerates sodium leaching.

These dispersion processes strongly undermine soil resistance to erosion. Faulkner et al. (2008) used these observations to explain the coupling of pipes to a rejuvenating channel in

Mocatan; a series of incisions reconnects slopes and channels causing an increase in the hydraulic gradient along the slopes; this, in turn, favors piping and pipe enlargement with the subsequent collapse of pipe roofs. Hence, lateral gullies can develop easily. The new (lateral) gullies have walls along which similar processes can occur, first piping, followed by gully formation again. This constitutes a feedback mechanism that ends a period of slope-base stability. Examples of this type of process can be found in many places where badlands exist, such as the *biancana* badlands of Tuscany (Torri and Bryan, 1997). Wilson (2009) discussed some of the processes involved in this pipe-gully interaction using laboratory experiments.

A basic classification for evaluating the risk of pipe erosion on the basis of the dispersion potential of a soil was given by Fitzpatrick et al. (1995) for soils in Southeastern Australia. They suggested that a soil is at risk of pipe erosion when the following condition is fulfilled:

$$EC < 0.062ESP + 0.33$$
 (22.15)

where

EC is the electrical conductivity at 25°C in a 1:5 soil:water suspension

ESP is the exchangeable Na percentage

Other criteria, including those to use in the field, were discussed by Bell and Walker (2000).

22.2.6 Shallow Mass Movement

Shallow mass movements are important in water erosion because (1) they are responsible for the evolution of rill and gully slopes during and between rainstorms; (2) mass movements may trigger gullies and pipes and *vice versa*.

Local mass movements of soil result from local severe degradation processes and are usually associated with other forms of erosion such as rills, pipes and gullies. In agriculture, mass movements inhibit farm operations by loss of accessibility, exposure of infertile subsoil and unprotected soil surface layers to splash and rill erosion, and net downslope movement of the soil mass. Gravity is the principal force producing slides, slips, slumps, flows, and landslides. At a particular water content soil becomes unstable and can slide downslope. Landslides and mass movements are usually classified by type and velocity of movement (Varnes, 1978). Rapid movements of soil mass over a distinct sliding surface are termed "landslides." Slower long-term deformations with a series of sliding surfaces and exhibiting viscous movement are termed "creep."

Generally mass movement occurs when the weight (shear stress) of the surface material on the slope exceeds the retaining ability (shear strength) of the material. Risk of mass movement is increased by erosion or excavation undermining the foot of a slope, loss of stabilizing roots through removal of vegetation, and increase in pore water pressure within the soil profile. Increased pore water pressure or greater water absorption may

weaken intergranular bonds, reducing internal friction, therefore lessening the cohesive strength of the soil and, ultimately, slope stability.

Usually slope stability is determined quantitatively by the ratio between available shear strength of soil mass and imposed shear stress computed along the assumed sliding surface:

$$F_s = \frac{T}{s} \tag{22.16}$$

where

 F_s is the stability factor and depends on the shape of the sliding surface and on the type of movement T is the shear strength (the sum of resisting forces)

S is the shear stress (the sum of driving forces)

Values of $F_s < 1$, $F_s > 1$, and $F_s = 1$ correspond to unstable, stable and metastable slopes. Considering the spatial and temporal variability of soil properties, values of $F_s > 1.2$ are considered satisfactory for stable conditions in a conservative analysis. Usually, sliding surfaces are supposed to be circular, planar or generic. Two-dimensional analysis is commonly used to evaluate overall slope stability (Huang, 1983). Basic inputs are slope transect, interface profile of the discontinuities present in the soil mass, mechanical properties of each stratum on the slope portion being considered, and the profile of the final phreatic surface separating saturated from unsaturated soil.

Mass movements may be classified using the following relationship (Janbu, 1973):

$$d_{i} = \frac{d}{L} \tag{22.17}$$

where

d is the maximum depth of the sliding surface *L* the length of the sliding mass (Figure 22.1)

Landslides characterized by $d_l < 0.05$ are considered planar movements with sliding surfaces subparallel to the slope. Higher values are typical of circular or pseudo-circular sliding surfaces.

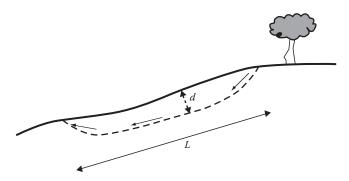

FIGURE 22.1 Shallow mass movement: definition of the d and L parameters.

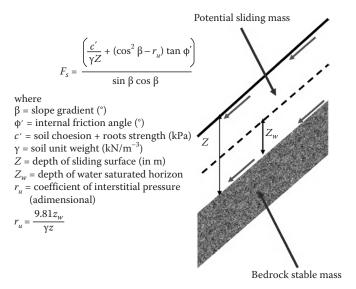

FIGURE 22.2 Planar shallow mass movement—infinite slope stability model.

For shallow mass movements, the infinite slope approach assuming planar movements (Figure 22.2) is commonly used. The stability factor may be evaluated from

$$F_s = \frac{\frac{c'}{\gamma z} (\cos^2 \beta - r_u) \tan \varphi'}{\sin \beta \cos \beta}$$
 (22.18)

and

$$r_u = \frac{9.81 z_w}{\gamma z} \tag{22.19}$$

where

z is the depth of the soil layer or the slip surface in the topsoil used to evaluate stability

 z_w is the height of the water table above the slip surface

 β is the local slope angle

 ϕ' is the angle of soil internal friction

c' is the internal cohesion of the soil

 γ is the unit weights of soil

Equation 22.18 applies to planar sliding of the soil mass where sliding surface and seepage flow are approximately parallel to the land surface. Such conditions only occur in some instances, whereas the infinite slope criterion is used for evaluating stability over large areas or watersheds. Some computer models use the infinite slope method under probabilistic and deterministic approaches (LISA) (Hammond et al., 1992).

The soil strength parameters φ' and c' are commonly measured in the laboratory on undisturbed soil cores, based on the Mohr–Coulomb soil strength criterion (Whitlow, 1990) or estimated indirectly from empirical correlations with penetrometer or vane test values measured in the field (Huang, 1983; Whitlow, 1990).

Particular situations such as concave-convex slopes, gully walls, tension cracks, thawing slopes, and vegetation effects necessitate modification of Equation 22.18. Alternatively, limit equilibrium methods should be employed for nonplanar slopes with tension cracks (Janbu, 1973). Several features, such as evidence of previous mass movement, poor vegetation cover, and linear features across slopes related to cracks or minor terracing in the landscape can indicate whether a certain area deserves study in order to assess the risk of mass movement. Old or dormant landslides characterized by long, uneven hummocky slopes, cracks, and fissures and bent tree trunks on steep slopes indicate a history of mass movement. Vegetation has the effect of reducing shallow mass movements; roots add resistance to the soil if they pass through the sliding surface, fixing the potentially sliding portion to the layers underneath (Hammond et al., 1992). Sliding potential may increase if trees are rooted only above the sliding surface as previously discussed.

22.2.7 Other Factors and Processes Affecting Soil Erosion by Water

22.2.7.1 Vegetation

We have already pointed out that vegetation has a strong influence on soil erosion, intercepting and redistributing rain water. Vegetation has an effect on linear erosion through an increase in the hydraulic friction factor (Manning *n* and Darcy–Weisbach *f*) and in the soil shear strength. The detachment rate, as expressed in Equations 22.9 and 22.10, shows that the factor β decreases exponentially with increasing soil shear strength. As root density increases soil resistance, then erosion decreases with it (De Baets et al., 2008). Roots also affect mass movements when they pass through the surface of failure. Roots increase macroporosity and, hence, enhance water infiltration and decrease overland flow. Protecting soil surface against direct drop impact (e.g., litter, low grasses, moss), vegetation reduces soil crusting. As the environment protected by vegetation is more suitable to life, vegetation also enhances the positive effects of microorganisms, fungi, etc., on soil structure and soil resistance to erosion (e.g., Salvador Sanchis et al., 2008).

Due to its dynamics, natural vegetation is also a candidate for driving changes in soil characteristics relevant to erosion. Particularly on abandoned land, but also on overgrazed or degraded land (Trimble and Mendel, 1995), species composition changes with time as local conditions stabilize or improve. An example of integrated approach to soil erosion and vegetation dynamics is the PATTERN model (Mulligan, 1998). It uses high temporal resolution meteorological data to calculate water budget and vegetation growth. It simulates seed dispersal, which is usually absent in most models that deal only with cultivated crops. For medium- to long-term studies and predictions it is also necessary to include the effects of animals and of the dynamics of animal species on plants and plant succession (Smith et al., 2003).

A long-term effect of vegetation is the enrichment of the organic matter component of the soil, which, in a healthy soil, becomes a ligand, which increases soil aggregate stability. Frequent tillage operations or other sources of disturbance (such as overgrazing) interfere with the positive effect of vegetation and make the soil more erodible.

Soil is dynamic, with changes that accumulate over years or with seasonal variations. This is apparent in rangeland soil (e.g., aggregate stability seasonal variation—see Salvador et al., 2008, for a short review) but it is much more evident in cropland. Many system parameters, such as the soil erodibility factor of USLE, show seasonal dynamics, which can be inferred through mean monthly air temperature oscillation during the year (Salvador et al., 2008). Bulk density of cropland soils changes because soils after tillage resettle and most of the tillage macropores are reduced to smaller sizes, aided by rainfall and cycles of wetting and drying (Knapen et al., 2008). with modifications of erodibility, shear strength and aggregates stability.

22.2.7.2 Rock Fragments

When non-erodible (or scarcely erodible) grains, such as rock fragments, are present, the soil surface is carved by erosion into pedestals surmounted by grains. Erosion can continue until a pavement of rock fragments protects the soil from any further loss. The first direct effect of rock fragments is that of intercepting raindrops. Consequently, drop detachment decreases proportionally to the fraction of soil surface covered by rock fragments. A further effect is that of concentrating runoff between stones, locally increasing the flow capacity for detachment and transport. More specifically, water flowing around isolated rock fragments excavates a horseshoe-shaped incision on the upstream side of the stone due to whirls (Poesen et al., 1994). The rock fragments can be considered isolated from other fragments until they cover less than 20%-25% of the surface. After such a threshold, eddies interfere and tend to disperse their energy onto nearby non-erodible rock fragments rather than erodible grains. As a consequence, erosion may initially increase and then decrease while the rock fragment cover increases. The initial possible increase in erosion occurs following the balance between reduced drop detachment and increased overland flow detachment. Reduction occurs when rock fragments are not embedded into the soil so that water can infiltrate under it, hence maintaining a high infiltration rate and a low overland flow. On the contrary, erosion may increase when the rock fragments are embedded into the soil surface so that overland flow per unit of erodible soil surface

Rock fragments also show a protective effect in reducing rill erosion. This occurs because rock fragments are often too large to be entrained by the flow (e.g., Rieke-Zapp et al., 2007). Selective erosion leaves more and more rock fragments on the soil surface, armoring it. This effect is clearly shown on soil erodibility (Salvador et al., 2008).

22.2.7.3 Erosion due to Tillage and Land Leveling and Its Interaction with Water

Customary farming activities are an important source of change in soil characteristics and in local slope morphology. For this reason it is important that a person surveying an area should be aware of the modification caused by such practices and of their effects on soil erosion. This is also important in scenario analysis, for example, when a change of land use or 10 years of tillage are hypothesized to occur.

Whenever soil is cultivated, a displacement of the tilled layer takes place (Govers et al., 1994; Van Oost et al., 2006). The term "tillage erosion" is used when the soil translocation produces a net soil loss or a net soil accumulation locally (Figure 22.3). Tillage erosion is influenced by slope gradient, depth and speed of tillage, type of tillage tool used, and direction with respect to the local slope gradient (Torri and Borselli, 2002; De Alba et al., 2006). Tillage is responsible for the creation of false terraces at field borders and of macro-pedestals under isolated poles or trees.

Tillage erosion rates are comparable to or higher than soil erosion by water, even if the net erosion due to tillage is concentrated mainly in convex morphology and deposition in concavities. So, where soil erosion by tillage is maximal, soil erosion by water is minimal (Van Oost and Govers, 2006). Annual erosion rates due to tillage often range between 10 and 50 Mg ha-1 year-1 (Van Oost and Govers, 2006). In some cases, localized in convexities, detailed surveys indicate a lowering rate of soil surface ranging approximately between 2 and 4cm year-1 due to deep ploughing (Borselli et al., 2002). For the purpose of comparison with the customary unit of measures used in soil erosion, these values correspond to losses ranging between 200 and 600 Mg ha⁻¹ year⁻¹. These values indicate that soils in cultivated fields can change their properties (including soil resistance to erosion and infiltration capacity) in a few years when the tillage tool starts cutting into a B or C horizon and mixes it with the original Ap material.

Let us now examine land leveling. Since the beginning of agriculture, farmers have acted to adapt plants and slope morphology to their needs. Today, reshaping the slope morphology has become a sort of *condicio sine qua non* for growing new crops in many areas of the world. The earth movements (land leveling) change the slope gradients, the concentration lines of surface and subsurface water fluxes, and the shapes and sizes of local catchments. The depth affected by earth movement often reaches the *C* and *R* soil horizons. Generally, upslope soils and soils on convexities are cut and the material moved to concavities or

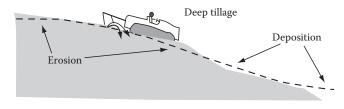

FIGURE 22.3 Soil erosion by tillage due to deep ploughing.

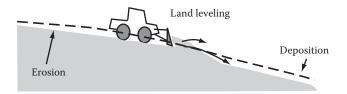

FIGURE 22.4 Land leveling: soil redistribution, erosion, and deposition.

down the slope (Figures 22.3 and 22.4). These processes produce a truncation of original soil profiles in the convex surfaces and a degradation of soil properties and qualities (e.g., water conductivity, organic matter content, fertility, erodibility).

Tillage erosion and land leveling cause soil depth and soil characteristics to be modified within the slope. This modifies the spatial variability of runoff generation and often promotes larger runoff concentrations. Rill and ephemeral gully formation is thus generally enhanced. The concavities that have been filled with additional material are increasingly unstable; subsurface water fluxes concentrate water in the same concavity, but in this case, the weight of the soil column above the potential sliding surface is larger, enhancing the risk of shallow mass movements (Borselli et al., 2006). Increased frequencies of ephemeral gully generation and of shallow mass movement trigger further land leveling, establishing positive feedback mechanisms. Row crops can intensify the mechanism because each row acts as a preferential flow path, further concentrating runoff.

We should consider that 1 m of land leveling corresponds to 13,000 Mg ha⁻¹ of net erosion or accumulation, which is at least two orders of magnitude more intense than any concentrated erosion or sedimentation rate due to overland flow. Land leveling often has on and off-site effects produced by water erosion on fresh leveled surfaces: the extremely high erodibility of the leveled surface, coupled with an intense rainfall can produce instances of extreme erosion with total soil losses up to 400–600 Mg ha⁻¹ (Borselli et al., 2006).

A further implication linked to tillage and leveling is that an intensively tilled or recently leveled slope hides gully and mass movement occurrence, presenting a landscape that appears to be stable and well managed. To understand the real processes occurring in such a slope, a surveyor must use sets of historical photos (air photos, now also very high definition satellite images) to identify processes and hazards.

22.2.7.4 Wildfires

Wildfires damage vegetation and litter and can severely affect the soil (e.g., Giovannini and Lucchesi, 1997; Rengasamy and Sumner, 1997). Soil biota and soil organic matter can be destroyed or damaged, clay minerals modified, and water repellency generated or enhanced (e.g., De Bano et al., 1976; Giovannini and Lucchesi, 1983).

The heat developed by the fire causes textural changes through the aggregation of clay and silt particles into sand sized

grains resistant to the chemical and physical actions of water (Giovannini and Lucchesi, 1997). This leads to changes in soil structure with disintegration of macro-aggregates and migration of micro-aggregates through the profile (Giovannini, 1994; Ubeda and Sala, 1998), which, in turn, modifies the water retention properties of the soil profile. If temperatures reach sufficiently high levels, clays are denatured and lose their charge rendering them less dispersible (Rengasamy and Sumner, 1997). On the other hand, high temperatures can cause the distillation of organic matter. The nonvolatile compounds, in particular, move downward into the soil profile until they condense in a cooler portion of the soil. Under certain conditions of combustion and soil moisture content, a subsurface hydrophobic layer develops (De Bano et al., 1976; Giovannini and Lucchesi, 1983). Usually, these transformations give rise to changes in the behavior of burnt soils with loss in water storage capacity, and changes in the rate of infiltration and hydrophobic behavior (DeBano et al., 1970; Le Bissonnais, 1996). The intensity and type of deterioration caused by fire are closely related to the physical and chemical properties of the soil that is burnt, above all texture, size, and composition of the structural aggregates (e.g., Mataix-Solera and Doerr, 2004). The net effect of these mechanisms is a decrease in organic matter content in the soil surface layer and an increase in water permeability, which is contrasted by an increased in hydrophobicity. If a hydrophobic layer forms, water permeability decreases dramatically and overland flow production is enhanced.

These modifications are accompanied by a decreased stability of soil aggregates. Usually this favors the decrease in infiltration capacity but mainly causes soil erodibility and erosion to increase substantially. Measurements of soil erosion and runoff in equipped plots showed that maxima are reached where the fire had been most intense (Rubio et al., 1997). Branson et al. (1981) and, more recently, Pierson et al. (2008) reported values indicating that the predominant effect of fire is to reduce infiltration and increase erosion. In particular, soil loss (on an annual basis) after a moderate to intense fire may increase by something between 2 and 10 Mg ha⁻¹, with exceptional values of more than 100 up to 500 Mg ha⁻¹ in a fine sandy loam over pumice.

The powerful effect of fire on aggregate stability is used by Varela et al. (2010) who based their estimates of erodibility modification caused by fire on the modification of soil aggregate stability in water. Following the intensity of a fire and of its immediate consequences, the local ecosystem requires time to recover, sometimes several decades even in the absence of other wildfires (Andreu et al., 2001). Hence, it is important to be able to recognize where erosion can be more intense in order to identify sites where to protect the soil and help the system to recover (Varela et al., 2010). It is an important goal to study the soil properties discussed so far (particularly induced hydro-repellence, new soil-aggregate characteristics, and colloidal fraction modification) and describe them through appropriate algorithms in order to improve runofferosion models.

22.3 Soil Erosion Models for Scenario Analysis

Reliable scenario analyses can be conducted with the use of models. Models are needed because erosion is determined by many processes and factors interwoven in a non-linear fashion. Practically all models can be used for scenario analysis. Some are more reliable and easy to adapt to newly designed situations than others.

The first model able to estimate soil loss over a wide range of situations was the USLE (Wischmeier and Smith, 1965) initially limited to the United States, East of the Rocky Mountains, and later extended to the Pacific coast (Wischmeier and Smith, 1978). The model, which was recently revised (RUSLE), is expressed as (Renard et al., 1997):

$$A = RKLSCP (22.20)$$

where

A is the average annual soil loss over a 20–22 year period

K is soil erodibility

R is rainfall erosivity

L is the field length factor

S is the gradient factor

C is the crop and management factor

P is the effect of the soil protective practices

Soil erodibility is determined experimentally as the soil loss per unit *R* measured on a 22.1 m long plot with a 9% uniform slope gradient that must be kept under continuous fallow with frequent up and down cultivations to remove weeds and erosion features. Erosivity is defined as

$$R = 0.01 \sum EI_{30} \tag{22.21}$$

where

E is raindrop kinetic energy over the storm (MJ ha⁻¹) before hitting either the soil surface or vegetation

 I_{30} (mm h^{-1}) is the maximum rain intensity over 30 min during the storm

In other parts of the world, maximum intensities over shorter periods have been found to be better suited for predictions.

Given that RUSLE relies on generally available or easily found input data, it is often used outside its proper application scale (field scale). Terranova et al. (2009) exemplify this type of application of RUSLE at a territorial level, where the local erosion value becomes a sort of local index of potential erosion.

Recent reexamination of a worldwide erodibility dataset has shown the marked effect of climate, with soils developed in cooler climates being more erodible than soil developed in warmer climates (Salvador et al., 2008).

Many models have been developed since USLE was first published, many of which are much more physically based. Merritt et al. (2003), Singh (1995), and Torri et al. (2007) described more than 30 different models. Reviews are always relatively inaccurate and rarely up to date unless the models they are describing are old models on which nobody is working anymore. Moreover, a model cannot be said to be properly known until its physics (i.e., the approximations contained in each model's components) and its mathematics (especially the routine of numerical approximation) are known together with the code that translates them into the computational reality of the model. Generally, the manuals that are distributed with the models are not sufficiently informative. Models are a synthesis of the knowledge on a given subject. Their submodels (algorithms) represent processes that feed into each other well or need bridges, types of heuristic solutions to missing links between processes. Obviously not all we know on a subject can be put into a model. Hence, models are approximations of our knowledge at a given moment.

Distributed models usually bring in computational problems. This is an aspect that generally is not described in manuals but must be known because a robust numerical approximation is a prerequisite for any decent prediction. The problems are usually due to the numerical approximations needed to solve the equations that guarantee conservation of mass, momentum, and energy in the fluxes from cell to cell. All this imposes limits on the time-step length, based on cell spatial size and local discharge: roughly, all that comes out of a cell during one timestep cannot travel beyond the downslope cell during the same time-step. Information on these math problems are usually scanty or completely missing. The LISEM manual mentions Courant's condition only to state that it is the user's responsibility to understand if the calculations have actually converged at all stages, in every cell (http://www.itc.nl/lisem/ > lisem basic > basic theory > kinematic wave > routing procedure in LISEM). Other models, such as KINEROS and EUROSEM, in their earlier versions, advised users to change time-step lengths when convergence was at risk. As the transfer of energy and matter often requires applications of numerical methods, approximations become significant and weak tests on convergence allow major errors in estimates. A review of methods for modeling kinematic wave and water transfer can be found in Singh (1996).

The scale at which a catchment is represented affects the way in which processes can be mathematically described because the model scale is usually inadequate to surrogate the process scale (e.g., cellslope gradient generally decreases with increasing cell size). Once the range of scales at which a given model is set to work is decided, inputs and outputs are defined. Many relevant input parameters of a hydrological-erosive model depend on the interaction between different types of information. For example soil parameters have a daily, weekly or seasonal variation and are modified by the cumulative effects of erosion, land use and soil management. If the model runs over several months, vegetation must be examined in relation to temporal dynamics. If land use or management changes are included, then soil parameter values also need adjustment. As already discussed, land leveling and

tillage erosion may also require morphology to be adjusted. If climatic changes are involved, then the resilience of natural vegetation to withstand the new situation must also be considered.

Landscapes must be properly described in order to model flows (water and sediment) over the terrain. This requires (1) the division of landscape (terrain surface and subsurface) into a set of connected elements; (2) the use of conservation of mass, energy and momentum within neighboring elements, of the fluid as such and of the different components of the fluid (sediment and water); and (3) the identification of flow paths.

Cascading planes, raster and triangulated irregular network (TIN) are three different representations of the landscape. They can produce different outcomes and may need different degrees of data aggregation. A "cascading planes" representation requires the user to simplify the landscape into series of planes and channel segments. A raster representation is obtained by automatically subdividing the landscape into a series of equal square cells. The TIN approach allows the description of the landscape using a variable planar density of coordinates.

Linear forms such as cliffs, vertical gully walls or terrace borders, are either poorly or not represented in the above-mentioned systems. They have to be taken into account in the model software. Simulations, including local landscape modification processes (e.g., gully or rill generation, land use change, years of tillage) are difficult to represent with cascading planes without the need to manipulate them during the simulation period. This type of simulation is better achieved if the landscape is represented as a raster or a TIN (Hofierka et al., 2002; Shary et al., 2002; Jetten et al., 2006).

Major models (continuous, distributed, and physically based) are those derived from the Système Hydrologique Europeenne (SHE, Abbot et al., 1986; MIKE SHE, Refsgaard and Storm, 1995; SHESED, Bathurst et al., 1995). In a raster landscape the soil is described with its horizons, through which water can flow vertically (Richards equation). When saturation is reached, or a water table is met, then the flow runs parallel to the saturated surface. Both saturated and hortonian flow can be described. It is not clear how well they perform in the presence of cracks and other macropores that cannot be described by Richards equation.

Cascading planes landscape representation is used in several models (e.g., OPUS, Smith, 1995; WEPP, Flanagan and Nearing, 1995; EUROSEM, Morgan et al., 1998) OPUS is a continuous simulation model with time steps varying to match process dynamics and numerical approximations. WEPP too, is a continuous and event-based model, containing a noticeable series of innovations derived from WEPP specific research. A raster representation is used in models such as ANSWER (Beasley et al., 1980), which, initially developed for describing single rainfall event, is now a continuous physically based simulation model.

A single-event model KINEROS (Woolhiser et al., 1990) was developed to test different research hypotheses such as transport equations. KINEROS was also used as a basis on which to develop EUROSEM (Morgan et al., 1998). Its hydraulics is limited to hortonian overland flows (rainfall exceeding infiltration intensity). Its numerical approximations converge fairly well.

KINEROS evolved into a KINEROS2 model (Smith et al., 1999). Still based on cascading planes, it has a better infiltration routine based on a 2-layer infiltration equation (Smith, 1990).

LISEM (De Roo et al., 1996,) uses most of the equations developed in EUROSEM for erosion. LISEM describes rills and ephemeral gullies, (Jetten et al., 2006) while flow direction can follow either the slope gradient downslope direction or the direction of tillage rows (Takken et al., 1999, 2001).

The model SIMWE (Mitasova et al., 2001) presents original solutions of the equations responsible for water and sediment fluxes, treated with the stochastic methods described by Gardiner (1985).

The European project MEDALUS produced two models (MEDALUS and MEDRUSH), which include long-term modification of soil and vegetation (Kirkby et al., 1998; Mulligan, 2004). Both models are targeted to the Mediterranean environment in natural or seminatural (i.e., abandoned) conditions. Recent European funded research has produced PESERA, which works on cells 1 km² in size, disconnected, in which the erosion processes take place without export or import of sediment from adjacent cells (http://pesera.jrc.it; Kirkby et al., 2008). The TEST model (van Dijk and Bruijnzeel, 2003) deals with soil erosion in terraced lands (bench terraces).

Common GIS software (GRASS, IDRISI, and ESRI) can calculate parameters linked to runoff, such as the catchment area of each pixel. This allows the use of simple algorithms for sediment production in a distributed way (Moore and Burch, 1986a, 1986b, 1986c; Mitasova et al., 1995; Desmet and Govers, 1996). Examples are RUSLE3D and USPED.

Other models (e.g., GEOWEPP) are equipped with a special interface for using GIS-based data-sets, GRASS can produce data for many models that are integrated in it: For example, ANSWERS (Rewerts and Engel, 1991), KINEROS and SIMWE. Siepel et al. (2002) proposed a simplified erosion model running in a GIS environment in which rills are included as a separate contributing process to erosion. In Table 22.1 some links to GIS based models are given.

The hydraulics of the quoted models usually does not deal properly with cracks or fluxes through macropores. Hence, tunneling and piping cannot be described despite their importance.

Models are often afflicted by problems of this kind, that is, missing processes. Most ignore feedback on soil characteristics and flow connectivity. As missed modifications tend to accumulate, divergences between simulation and reality are bound to increase with simulation time length. Hence, care must be taken in choosing a model and it is certainly better not to make a decision without having first read carefully what the model contains and how it works.

Generally, models do not describe the effects of other causes of degradation and erosion that can severely affect the way that the soil and landscape respond to intense rainfall. Examples are overgrazing, which can rapidly worsen soil characteristics, tillage, and land leveling, both causing soil degradation and morphology modification. When the crop is of a type that grows underground (e.g., beetroot, potatoes), soil is exported during harvesting (Poesen et al., 2001; Ruysschaert et al., 2004). This also causes a soil profile truncation in a short time span. In all these cases, soil characteristics must be changed accordingly.

Tillage erosion is already the core process of some models among which one of the most evolved is WATEM (van Oost and Govers, 2000). It is spatially distributed and simulates erosion and deposition by water (with USLE-based algorithms) and tillage translocation in a two-dimensional landscape (raster type).

Land leveling, on the other hand, is absolutely ignored. The only attempt has been made by Borselli et al. (2003), but no full description of the model (BULLRUN) is available.

22.4 Conclusions

Water erosion is characterized by many processes induced by raindrops, overland flow, pipe flow, and mass movements. The main equations describing those processes highlight the main soil characteristics involved directly: grain size, colloidal content, chemical composition of soil solution, structural stability, infiltration capacity, rock fragment content, soil surface roughness, and soil profile characteristics. In addition, factors such as slope morphology, catchment size, flow concentration lines, vegetation, land use, and land use techniques are the cofactors that can control or speed up erosion. Additional processes such as soil erosion by tillage and land leveling have a severe impact on soil erosion by water.

In order to use soil in a sustainable way and to conserve it for future generations, soil erosion processes must be better understood together with all their links to the biophysical system of which the soil is an important part. A major tool for soil conservation and land-use planning is scenario analysis, Current erosion models are tools for helping experts to devise possible conservation measures and scenario analyses although they must be used with caution, bearing in mind that they are just approximations.

Acknowledgment

The authors are grateful to Mark Nearing and Jean Poesen for their suggestions that helped in improving the original manuscript.

23.1 Introduction

Wind erosion is a basic geomorphologic process that erodes the land surface and shapes yardangs, ventifacts, pedestal rocks, blowouts, ergs, dunes, lag deposits, desert pavement, and desert armor (Thornbury, 1957). On every continent, aeolian features document the persistence and magnitude of wind forces. While the transport capacity of the wind is much less than that of water, dust concentrations may exceed 6000 µg m⁻³ in severe events (Song et al., 2007). Dust accumulations over a 16 year period in the Mojave Desert varied from 2 to 20 g m⁻² year⁻¹, but were affected by amount and seasonal distribution of rainfall (Reheis, 2006).

The recorded history of wind erosion extends over a few hundred years; however, peat bog cores in southern Chile indicate that dust accumulations were effectively constant over a period of six millennia (Sapkota et al., 2007). A chronology of dust storm activity in Northern China over the last 1000 years showed two marked dust peaks between AD 1430–1570 and between AD 1770 and 1990 in the arid west. In China the dust storm maxima occurred at AD 1140–1220, 1430–1500, and 1680–1780 (Yang et al., 2007). All of these were during periods of cold–dry climatic conditions.

Wendelin reported a purple or dark red rain in Brussels in 1646 (Wendelin, 1646). The red rain was the result of dust deposition on October 6, 1646, and caused considerable concern. Based on current knowledge, red rains in Europe may result from dust produced by storms in Africa (Stout et al., 2008).

In the wind erosion process, fine particles and nutrients are removed, leaving coarse particles on the eroded surface.

As the surface continues to erode, the remaining soil becomes less fertile. The loss of fertile soil material from agricultural lands degrades the soils in the source area, reduces crop production, and further intensifies wind erosion. Dust in the atmosphere may affect air temperatures, cloud formation, and convectional activity (Goudie, 2009). Hurricane peak intensity in the North Atlantic Region has been linked to dust outbreaks in the Sahara (Wu, 2007; Wong et al., 2008). Dust clouds contaminate the atmosphere in the transport area and impact citizenry throughout the depositional area. It is not uncommon for the source and depositional areas to be thousands of kilometers apart. Dust-emission models (Zhang et al., 2003; Tegen et al., 2004) suggest that the global dust load is primarily related to climate change and not in response to land use changes.

Erosion control practices that minimize erosion have attracted farmers long before the basic processes were understood. In 1790 Deane used hedges and locust trees and in 1824 Drown used the addition of 50–80 mm of clay to blowy sand soil surfaces in efforts to reduce wind erosion in the United States (McDonald, 1971). Deep plowing to increase clay content of the surface soil controls wind erosion on thousands of hectares of sandy soil in the Southern Great Plains (Chepil and Woodruff, 1963). The benefits of deep plowing persist for several years, depending on management practices (Fryrear, 1984). Straw barriers in a checkerboard pattern (Xu et al., 1982), raised fences (Liu et al., 1983), or forest belts, also called shelterbelts (Dong et al., 1983), have been used in China to protect railroads and highways from blowing sand. Shelterbelts are used in India to reduce wind speeds, erosion, and evaporation losses (Gupta et al., 1981). The success of

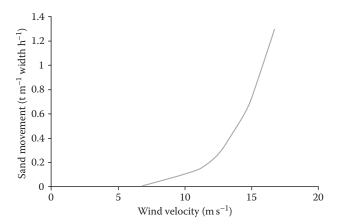

FIGURE 23.1 Transport flux of sand as a function of wind velocity. (Reprinted from Bagnold, R.A. 1941. The physics of blown sand and desert dunes. Methuen, London, U.K. Fig. 22. With kind permission of Kluwer Academic Publishers.)

shelterbelts depends on dominant erosive wind directions, sufficient annual rainfall to sustain the trees, and other potential uses of the trees (lumber, pulpwood, firewood, etc.). Any system that reduces the speed of the wind at the soil surface can significantly reduce soil erosion (Figure 23.1).

Wind erosion concerns can be grouped into three categories: environmental, agricultural, and transportation (Greeley and Iverson, 1985). Environmental concerns include effects of dust on human, animal, and plant health and on visibility and climate. Agricultural concerns include the impact of soil erosion by wind on the sustainability of agricultural production. Transportation concerns include reduced visibility from blowing soil on highways, railroads, and airports.

23.2 Mechanics of Wind Erosion Processes

Wind is defined as the motion of the atmosphere relative to the surface (Greeley and Iverson, 1985). As wind flows over the land surface, the surface exerts a drag such that an atmospheric surface boundary layer approximately 1 m thick is formed. This atmospheric boundary layer impacts the detachment (also called deflation), movement, and deposition of soil particles. When soils erode, the wind is turbulent and turbulence facilitates the transfer of momentum from the wind to the soil surface and exerts a shear effect on the surface. This shear or friction can be computed from wind speeds as follows:

$$\tau = \rho(U_*)^2 \tag{23.1}$$

where

 τ is the friction, dynes m^{-2} ρ is the air density, g m^{-3} $\it U_{*}$ is the friction velocity, m s^{-1}

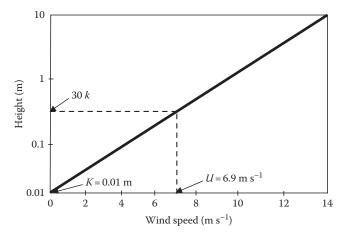

FIGURE 23.2 Determining aerodynamic roughness (k) and drag speed (U_*) graphically from plot of wind speed and height of wind speed measurement ($U_* = 6.9/8.493 = 0.8124 \,\mathrm{m \ s^{-1}}$).

Friction velocity can be computed by

$$U_* = \frac{U_z}{5.75 \log(z/k)} \tag{23.2}$$

where

 U_{\star} is the friction velocity, m s⁻¹ U_z is the wind speed at height z, m s⁻¹ z is the height where U_z is measured, m k is the aerodynamic surface roughness, m

Shear velocity can also be determined graphically using the relationships in Figure 23.2. The wind speed (U_z) is plotted as a function of the \log_{10} of the height (z). From this plot the aerodynamic surface roughness (k) and friction velocity (U_*) can be determined at the intercept and slope, respectively.

The relationship between speed and height (Equation 23.2 and Figure 23.2) is valid for clean air and neutral atmospheres. As the concentration of transported material increases, the relationships are no longer valid (Anderson et al., 1991).

Weather systems that erode soils vary in their time frames, space scale, and predictability. The author's estimates are listed in Table 23.1 and may not be valid for all regions of the world.

Dust devils are very common on Earth and on Mars, and are an abbreviated wind–sand transport system that may be numerically modeled (Hess, 1973; Fernandez, 1997). Within the dust devil, the moving particles may become electrically charged to the point of causing electromagnetic interferences (Huang et al., 2008b). The sign of the electrical charge is negative when the diameter of sand particles is smaller than 250 microns and positive when diameter is larger than 250 microns (Zheng et al., 2003). The dust devil is a common sight in semiarid regions, but the time is short and spatial scales are very small.

On Mars dust storms are considered the seeds of global dust storms that may even engulf the entire planet (Hess, 1973). The haboob is a very dramatic cloud of dust that appears to roll over the landscape. While a haboob can blot out the sun for short periods of time they usually do not cover as large an area or last Wind Erosion 23-3

TABLE 23.1 Hierarchy of Weather-Duststorm Systems

Duststorm	Weather System	Duration Time (h)	Aerial Scale (km)	Predictability
1. Dust devil	Microtemperature differences	0.1-0.5	0.01-0.50	Observe only in real time
2. Haboob	Thunderstorm downdraft into dry air, that is, gravity flow	0.05-6	25–75	1–12 h
3. Severe mountain downslope windstorm	Complex terrain enhancement of downward transport of midtropospheric momentum	0.5–18	25–250	12-36 h
4. Frontal	Gravity flow, pressure gradient with dynamic assist	1-8	500-1000	24-48 h
5. Cyclogenic				
a. Low level jet	Boundary layer thermal differences, momentum transfer within shallow adiabatic planetary boundary layer	6–12	500-1000	24–48 h
b. Upper level jet	Deep adiabatic heating of troposphere through dynamic subsidence	8-24	500-1000	24-72 h
c. Surface storm circulation	Deeper-gradient winds	8-18	50-150	12-36 h
d. Severe mountain downslope windstorm	(Mechanism No. 3 above) ^a			

^a The mechanism for the cyclogenic severe mountain downslope windstorm is the same as for the severe mountain downslope windstorm, but the duration is usually longer and the aerial scale is generally larger.

as long as dust storms produced by down slope, frontal, or cyclogenic weather systems (Table 23.1). Thirty years of dust storm data at Big Spring, TX, were analyzed. The average number of storm days was 26 per year with an average of 192 h with dust per year. Severe storms with visibilities of less than 300 m produced an estimated 54.9% of the total dust load with 11% of the total dust hours. Most of the dust storms included in these analyses resulted from frontal weather systems (Fryrear, 1981).

23.2.1 Wind Speed

Wind erosion is possible when the velocity of the wind at the soil surface exceeds the threshold velocity required to move the least stable soil particle. The detached particle may move a few millimeters before finding a more protected site on the landscape. An exception would be the direct suspension of dust without saltation or creep, which may occur on some loessial soils (Kjelgaard et al., 2002). The wind speed required to move this least stable particle is called the static threshold (Bagnold, 1941). If the wind speed increases, soil movement begins. When soil movement is sustained, the dynamic threshold speed has been attained and the quantity of soil that can be transported by the wind varies as the cube of the velocity (Bagnold, 1941; Chepil and Woodruff, 1963). Many transport equations have been reported that include a term for wind speed (Greeley and Iverson, 1985; Sorensen, 1991).

Soil roughness, erodibility, wetness, surface disturbance, and crop residue quantity and orientation are parameters that impact the vulnerability of soils to wind erosion. If the erodible soil surface is covered with vegetation or residues from a previous crop, the force of the wind is transferred to the nonerodible cover and erosion is controlled. Unfortunately, rainfall in arid and semi-arid regions may be insufficient to grow enough vegetation to protect the soil. Soils in these regions must be protected with other methods or the soil may erode until a desert pavement is

formed. With deep sands, the surface may never stabilize and active sand dunes will dominate the landscape.

Computation of friction velocity from wind profiles during severe wind erosion events is difficult because of the influence of soil material in the wind profiles. Soil particles may roll over the surface in a transport mode called creep, may bounce over the surface in saltation, or may float over the surface in suspension (Chepil and Woodruff, 1963). Chepil (1941) reported that saltation movement reduces momentum and speed of the wind. The greater the concentration of moving sand grains, the greater the apparent wind speed reduction near the ground (Chepil and Milne, 1941). Anderson et al. (1991) also reported that the presence of sediment transport in the windstream influences the wind speed in the boundary layer. Sand flux frequencies respond to fluctuations in wind frequencies less than 0.03 Hz (Shi et al., 2008).

For every soil condition there is a minimum wind speed called dynamic threshold that initiates sustained soil movement. Plant residues and soil roughness increase the threshold wind speed, but soil wetness temporarily stabilizes the soil surface (Saleh and Fryrear, 1995). Any non-erodible material such as stones or soil clods on the soil surface resists the force of the wind protecting a portion of the surface.

23.2.2 Soil

For mineral soils, the larger the soil particle, the greater the wind speed required to dislodge and transport the particle. Most field erosion occurs from a crusted surface with an abundance of loose sand. Individual sand particles are more easily eroded than particles with a median grain diameter of 40–160 microns. When median diameter of soil particles was <40 microns the coarsest particles were more easily eroded (Goossens and Gross, 2002). For the same wind, the transport rate may be twice as large for particles of mixed size as for particles of uniform size. The speed

and turbulence of the wind, density ratio of particles to air, and surface roughness dictate the largest soil particle that can be eroded (Chepil and Woodruff, 1963; Greeley and Iverson, 1985; Batt and Peabody, 1994). The erosion of soil aggregates by impacting sand particles increases with the square of the particle velocity. Increasing the size of the abrading particles from 125 to 715 µm gave a small increase in erosion of the soil aggregates (Hagen, 1984). Electromagnetic and static forces influence detachment and transport of small particles. When coupled with cohesive forces, micron size particles may coalesce into a larger aggregate less susceptible to transport by wind. Cyanobacterial biomass on California desert soils significantly increased surface stability, increased the threshold velocity, and reduced sediment yield (Belnap et al., 2006).

23.2.2.1 Soil Crust

After tillage the soil surface is loose and unconsolidated, but subsequent rainfall tends to create a consolidated zone in the soil surface called a crust. Crusts are more compact and mechanically stable than the soil below (Chepil and Woodruff, 1963). Crust may be more resistant to wind erosion than loose particles, but can erode when blowing soil particles are present in the wind stream. Crust properties important to estimate wind erosion include the thickness and stability of the crust layer, fraction of surface crust covered by nonerodible stones or clods, and the amount of loose erodible material present (Zobeck, 1991). Soil properties important in crust development include clay content (Chepil, 1958), CaCO3 and organic-matter content (Chepil, 1954a), and soluble-salt concentration (Nickling and Ecclestone, 1981). Not all crusts protect the soil from wind erosion. For soils with less than 3% silt and clay the crust formed is not a significant factor in reducing wind erosion (Rajot et al., 2003).

23.2.2.2 Dust Production and Transport

Wind-eroded particles are normally transported in one of three modes: creep, saltation, or suspension (Chepil and Woodruff, 1963). The specific mode of transport depends on the speed and turbulence of the wind and soil surface conditions. Creep particles $1000-2000\,\mu m$ in diameter roll along the surface. The creep component of the total soil flux can be a significant portion or almost zero. The texture and condition of the soil surface determines if large soil aggregates can roll over the soil or become trapped in microdepressions.

Saltating particles $100-1000\,\mu m$ in diameter move in a series of short hops depending on surface roughness, particle size, and wind speed. For speeds slightly above threshold, a saltation size particle may roll on the surface in a creep mode. For high wind speeds, saltation size particles may be transported at a considerable height in a mode normally called suspension. The saltating particles are largely responsible for the abrasion of soil aggregates and accelerate the erosion process until the wind has attained its maximum transport capacity.

Suspended particles up to $100\,\mu m$ in diameter represent the visible material in dust clouds that move into the upper atmosphere, and are subject to long-range transport. The size and binding energies between particles influence their release to the atmosphere, but

are not dependent on the soil texture or its mineralogical composition (Alfaro et al., 1998). As particles rise from the soil surface they may be subjected to numerous midair collisions in the saltation zone and the effect on wind speed is appreciable (Huang et al., 2007). Data suggest that relatively large particles may be transported considerable distances (Betzer et al., 1988). For most winderoded surfaces, the majority of the mass being transported is close to the soil surface. That portion in suspension may represent a small percentage of the total mass being transported but may have a major impact on air quality (Saxton, 1995, 1996; Stetler and Saxton, 1995). For soils the source of the material may be determined by the magnetic properties of the dust (Reynolds et al., 2006).

The vertical flux of dust divided by the horizontal flux is defined as the sandblasting efficiency (Gomes et al., 2003). The fine-textured soils may emit more vertical flux in relation the horizontal flux than coarse-textured soil, but the total quantity of material eroded by wind is much lower for the fine-textured soil. In NW Germany over a 2 year period dust emission due to tillage was four times the dust emission due to wind erosion. The total dust transport was 17.1 t km $^{-1}$ a $^{-1}$ in the first 10 m of the atmosphere. The horizontal dust flux increased from $50\,\mu g$ m $^{-2}$ s $^{-1}$ in January to $100\,g$ m $^{-2}$ s $^{-1}$ in April and then dropped to $20\,g$ m $^{-2}$ s $^{-1}$ in August (Goossens, 2004).

In the twenty-first century there is increased concern about air quality and how it is impacted by airborne particles. A Dust Production Model (DPM) (Alfaro and Gomes, 2001) was developed by combining a sandblasting model (Alfaro et al., 1998) with a saltation model (Marticorena and Bergametti, 1995). The DPM estimates the size and amount of aerosols from a given soil during a wind event. The model identifies the importance of aerodynamic surface roughness, dry aggregate size, and wind friction velocity.

23.2.2.3 Soil Erodible Fraction

For most agricultural fields, the soil is composed of sand, silt, and clay particles. Organic matter and CaCO₃ are constituents of soil that are important in describing the soil's susceptibility to wind erosion (Fryrear et al., 1994). Using the standard compact rotary sieve (Chepil, 1962) and a sample of the surface 20 mm of dry topsoil, the erodible fraction (*EF*) of the soil can be determined. The erodible fraction is that portion smaller than 0.84 mm in diameter easily eroded by wind. Several thousand samples were analyzed to develop the following equation:

$$EF = \frac{29.09 + 0.31Sa + 0.17Si + 0.33Sa/Cl - 2.59OM - 0.95CaCO_3}{100}$$
 (23.3)

where

EF is the erodible fraction (0.077-0.822) Sa is the sand % (5.5-93.6) Si is the silt % (0.5-69.5) Cl is the clay % (1.2-53.0) OM is the organic matter % (0.18-4.79) CaCO₃ is the calcium carbonate % (0.0-25.2)

The range of values in the dataset is in parentheses. The percentage of sand, silt, and clay are based on a dispersed mechanical

Wind Erosion 23-5

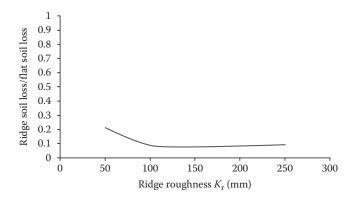

FIGURE 23.3 Soil loss ratio for various soil ridge roughness (k_r) values when wind is perpendicular to soil ridge. (From Fryrear, D.W. 1984. Soil ridges—Clods and wind erosion. Trans. ASAE 27(2):445–448.)

analysis procedure where clay particles are smaller than $2\,\mu m,$ silt particles are $2\text{--}50\,\mu m,$ and sand particles are $50\text{--}1000\,\mu m$ (Taylor, 1960).

With this equation, the potential erodibility of a mineral soil can be estimated from the physical and chemical properties. Equation 23.3 allows scientists to evaluate wind erosion control practices on small plots. If the soil surface is covered with erodible material, theoretically, erosion will continue as long as the wind speed is above the threshold. Large sand dunes can result, but even in desert dune regions, the interdunal area is normally composed of more resistant clay or rock material.

23.2.2.4 Soil Roughness

In most agricultural systems, the farmer tills the soil to prepare a seedbed, control weeds, or improve rainwater infiltration. Tilling normally increases soil surface roughness. Soil roughness may consist of uniformly spaced ridges or furrows and randomly distributed soil aggregates. The protection from soil ridges persists longer than random roughness, but soil ridge roughness is sensitive to wind direction. When the wind is perpendicular to ridges 0.06-0.25 m high, erosion may be controlled (Figure 23.3). The roughness of the soil surface other than that caused by clods or vegetation has been described as the Soil Ridge Roughness, K_r . When the wind is parallel to the ridge, the ridge is not effective in controlling wind erosion (Saleh, 1994). Aerodynamic roughness with ridges or soil aggregates controls or, at least, reduces soil erosion until rainfall smoothes the surface (Fryrear, 1984; Saleh et al., 1997). Roughness also reduces dust emissions from agricultural fields compared to dust from a flat, dry, loose soil (Batt and Peabody, 1994). A computational fluid dynamics model (CFD) has been used to describe particle stability depending on its position on a ridged surface (Huang et al., 2008a).

23.2.3 Plants

23.2.3.1 Seedlings

Emerging crop seedlings are sensitive to wind damage. In fact, each year thousands of hectares of crops are replanted because of windblown sand damaging or destroying the young crop

TABLE 23.2 Exposure Time to Windblown Sand for 25%, 50%, or 75% Survival

Source: Fryrear, D.W., and J.D. Downes. 1975. Consider the plant in planning wind erosion control systems. Trans. ASAE 18:1070–1072.

(Woodruff, 1956b; Skidmore, 1966; Armbrust et al., 1969; Fryrear and Armbrust, 1969; Fryrear, 1971; Armbrust, 1972, 1984). The first 4 weeks after planting are critical to many crops. Some crops are so sensitive that a 20 min exposure to windblown sand may destroy 75% of the seedlings (Table 23.2). As the plants mature, they are less sensitive to wind damage and the developing plant canopy affords some protection against wind erosion (Fryrear and Downes, 1975; Armbrust, 1977). Windblown sand injury delays maturity, increases susceptibility to diseases, and impacts the physiology of plants (Claflin et al., 1973; Armbrust et al., 1974; Armbrust, 1982). Completely defoliated cotton plants may recover due to increased shoot growth efficiency because the relative growth rate was related to net assimilation rate and not leaf area ratio (Baker, 2007).

23.2.3.2 Growing Plants

As crops mature, they can tolerate more sand injury and can reduce the wind speed at the soil surface (Fryrear et al., 1975; Bilbro, 1989, 1991, 1992). However, some crops such as cabbage or tobacco may be of inferior quality if sand is contained within the plant leaves (Fryrear and Downes, 1975; Armbrust, 1979).

23.2.3.3 Flat Residues

When crops are harvested, some plant material remains in the field. This residue or stubble has value as a source of nutrients for the soil, as animal feed, as building material or fuel, and as protection against wind erosion. Studies were conducted to determine the relationship between the proportion of soil surface covered with plant material and soil erosion (Fryrear, 1985; Bilbro et al., 1994). The available published data were combined into a single value that expresses soil loss ratio ($SLR_{\rm f}$) as a function of flat soil cover. The SLR allows one to test many different sizes and types of material and combine the results into one expression (Findlater et al., 1990). The $SLR_{\rm f}$ is the mass of soil erosion with residue cover divided by the mass of soil erosion without residue cover. Figure 23.4 illustrates that covering a 30% of the soil surface can significantly reduce wind erosion. These studies assume that the flat residues are uniformly distributed over the soil surface.

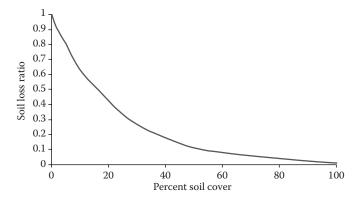

FIGURE 23.4 Soil loss ratio (soil loss with partial cover divided by soil loss for same soil without any cover) as a function of percent soil cover with nonerodible elements such as flat residues or rocks.

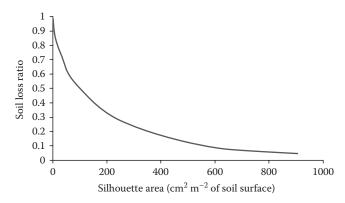

FIGURE 23.5 Soil loss ratio (soil loss with partial cover divided by soil loss for same soil without any cover) as a function of silhouette area; silhouette area is the profile area of all standing residues in a 1 m² area. (From Bilbro, J.D., and D.W. Fryrear. 1994. Wind erosion losses as related to plant silhouette and soil cover. Agron. J. 86:550–553.)

23.2.3.4 Standing Residues

When small grains, corn, sunflowers, soybeans, or sorghum are harvested, a portion of the crop residue remains standing in the field. Standing residues are at least six times more effective than the same mass of material flat on the soil surface (Englehorn et al., 1952; van de Ven et al., 1989; Bilbro and Fryrear, 1994) (Figures 23.5 and 23.6). These results emphasize that management practices that maintain residues in an erect position are more effective in controlling wind erosion than practices that flatten the residues or incorporate residues into the soil. The silhouette of a standing crop residue is the vertical area of the plants in $1\,\mathrm{m}^2$ of ground area. The effect of silhouette area on soil erosion is expressed as a soil loss ratio of standing residues (SLR_s). The SLR_s is the mass of soil loss with standing residues divided by the mass of soil loss when the surface is bare.

23.2.4 Humankind

Although wind erosion is a normal process, it can be enhanced by the irresponsible activities of humans (Chepil and Woodruff, 1955). When fragile soil or plant resources in arid regions are mismanaged by man's activities, restoration requires many years or may

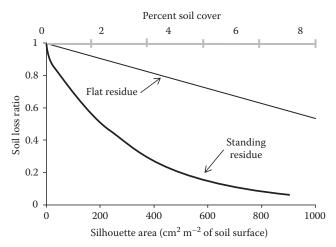

FIGURE 23.6 Comparison of soil loss ratio with the same quantity of residue standing as silhouette and flat on the soil surface. (From Bilbro, J.D., and D.W. Fryrear. 1994. Wind erosion losses as related to plant silhouette and soil cover. Agron. J. 86:550–553.)

be impossible. The mismanagement may be the result of surface disturbance from overgrazing, over cultivation, vegetative burning, woodcutting, salinization, or the use of animal dung as fuel instead of fertilizer (Middleton, 1987). When effective management practices are used, the soil, crop, and climatic resources can be utilized indefinitely. The most effective management practice must be flexible enough to respond to variable climatic conditions.

The clearing of forests, woodlands, or grasslands reduced soil fauna and organic matter and impacted soil temperature and soil permeability Strzelecki (1845). In addition, man-induced changes in surface and atmospheric conditions may impact local and regional climatic conditions (Saxton, 1995, 1996; Stetler and Saxton, 1995; Williams and Balling, 1996; Zobeck et al., 1996). Drift sand areas were preserved when undesirable vegetation was removed to expose the original sandy surface restoring the ecosystem (Riksen and Goossens, 2005). The impact of humans may be overshadowed by natural fluctuations in the global climatic system.

23.3 Modeling the Wind Erosion Process

The wind erosion process is a complex interaction of weather-soil-plants-man. To evaluate the effect of any single factor, the interactions between factors must be understood. Wind erosion models can be empirically, physically (also called process) or theoretically based. The application of empirically based models is limited to the range of conditions under which the model was developed. Also, empirically based models require carefully controlled experiments to develop the essential coefficients. Physically or theoretically based models may be more widely adapted but require that the theory and assumptions imbedded within the model are correct. Because of the complex interactions involved in wind erosion, the physical processes may not be well understood. For example, an analytical model developed by Sorensen (1991) utilizes processes for trajectory of the particles, wind

Wind Erosion 23-7

modification, and grain bed collisions. Formulae were derived for transport rate and flux of the sand grains from the surface into the air. In developing a conceptual transport model, McEwan and Willetts (1993) concluded that inaccurate wind speeds and sand trap inefficiencies may have been responsible for scatter in wind tunnel data. They also cautioned wind erosion scientists that extrapolation of sand transport rate formulae from the uniform laboratory wind tunnel conditions to field conditions may not be justified.

An empirically derived differential equation of dust concentrations in a thin layer near the ground to predict dust concentrations at the top of the surface layer was developed by Berkofsky and McEwan (1994). Unfortunately, the equation neglects horizontal transport, which is a major component of the wind erosion process; however, they recognized that the detachment plus a source term was inversely proportional to surface roughness.

While the above studies have been valuable sources of new approaches and have expanded our understanding of the wind erosion process, they do not have essential input parameters to develop a complete wind erosion model. Essentially all the models developed to date are a combination of physical, empirical, or theoretical approaches. Depending on the intended use the operator must determine if the model produces the desired output with the available input data.

23.3.1 Wind Erosion Equation

Wind erosion equation (WEQ; Woodruff and Siddoway, 1965) has been widely used to plan conservation systems and estimate annual soil erosion. WEQ was one of the first models to estimate soil erosion in the field using annual input values for weather, soil erodibility, soil roughness, field length, and crop residues. WEQ, which was developed from wind tunnel studies with limited field verification, assumes that the wind erosion process is similar to an avalanche of snow and debris rolling down a mountain (Chepil, 1957). As an avalanche rolls down the side of a mountain, the mass of material in the avalanche may increase as long as there is a source of snow and the slope is long and uniform. The quantity of material being transported by the wind can increase until the capacity of the wind to detach and transport soil has been reached (Bagnold, 1941; Chepil, 1957).

The WEQ consists of a functional relationship among five factors:

$$E = f(IKCLV) (23.4)$$

where

E is the annual soil erosion, Mg ha⁻¹
f is the functional relationship
I is the soil erodibility, Mg ha⁻¹ year⁻¹
K is the soil roughness factor
C is the climatic factor
L is the unprotected field length, m
V is the vegetation factor expressed as small grain equivalent

WEQ estimates average soil loss (note units of E and I) for an unprotected field length (L). If soil loss is divided by field length, the units are mass per unit width or an expression of transport mass.

Concerns that the climatic factor did not describe wind erosion in high or low rainfall regions were addressed and a new climatic factor was developed (Woodruff and Armbrust, 1968; Skidmore, 1986). The WEQ was modified for shorter time periods, but as stated by Bondy et al. (1980, p. 176), "no experimental data base exists for using the wind erosion equation for periods of less than one year."

WEQ was coupled with the Erosion Productivity Impact Calculator (EPIC) (Williams et al., 1984) to estimate daily wind erosion soil losses (Cole et al., 1983). The *I*, *K*, *C*, and *V* factors in WEQ are annual values, but in the EPIC wind erosion model they are considered constant for a single day. Estimates of wind erosion with EPIC were compared with WEQ estimates. When compared with observed erosion, WEQ under-predicted erosion 11 of 14 periods by as much as nine times (Van Pelt and Zobeck, 2004). While a model may perform satisfactorily under one set of conditions, it may not be suitable for all field conditions.

Sometimes models are used for conditions beyond the limits of the original research. For example, a Soil Quality Index (SQI) was developed using the WEQ model (Zobeck et al., 2008) even though the WEQ model has been shown to be inaccurate for many regions of the country and for many management systems (Fryrear et al., 2001).

23.3.2 The Pasak Model

A soil loss model reported by Pasak in 1973 was intended as a single event model (Holy, 1980):

$$E = 22.02 - 0.72P - 1.69V + 2.64Rr$$
 (23.5)

where

E is the erodibility, kg ha⁻¹ P is the nonerodible particles, % V is the relative soil moisture Rr is the wind speed, km h⁻¹

The lack of inputs for crop residues and soil roughness limits the use of this model. Also wind speed and soil moisture conditions are not constant during an erosion event.

23.3.3 Texas Erosion Analysis Model

The Texas Erosion Analysis Model (TEAM) developed by Gregory et al. (1988) is a computer program developed to simulate wind profile development and soil movement over multiple field lengths. The basic equation is

$$X = C(SU_{\star}^{2} - U_{\star t}^{2})U_{\star}(1 - e^{-0.000169A_{a}IL_{f}})$$
 (23.6)

where

X is the rate of soil movement at length $L_{\rm f}$, M L⁻¹ T⁻¹

 $C(SU_{\star}^2 - U_{\star t}^2)U_{\star}$ is the maximum rate of soil movement, which occurs when the surface is covered with fine non-cohesive material

C is a constant, which depends on width sampled and units used for U_*

 $L_{\rm f}$ is the length of unprotected field in the wind direction $A_{\rm a}$ is the abrasion adjustment factor

I is the soil erodibility factor involving soil shear strength

S is the surface cover factor, which expresses the amount of detachment energy at the top of the cover, which is transferred to the soil

 U_* is the friction velocity

 $U_{\star t}$ is the threshold friction velocity

The abrasion adjustment factor is computed using the equation:

$$A_{\rm a} = (1 - A_{\rm l})(1 - e^{-0.0072e^{0.00079 H_{\rm f}}})$$
 (23.7)

where A_1 is the lower limit of abrasion effect (assumed 0.23).

23.3.4 Wind Erosion Assessment Model

This process-based model developed in Australia is a combination of established and theoretical results (Shao et al., 1996). It synthesized research results on sand drift and dust entrainment, approximated quantitative assessment of wind erosion, and evaluated the current limits to our knowledge of the wind erosion process. The Wind Erosion Assessment Model (WEAM) model does not predict the evolution of soil surface properties due to wind erosion, natural weathering processes, or management interventions. WEAM treats erosion of a dry, bare soil in a given wind. To model daily or annual erosion, it is essential that changes in soil and crop conditions be described by the model.

When coupled with large computers, WEAM does have the capability of estimating the movement of large dust clouds across complex landscapes. Input requirements are such that GIS or other information databases are essential to utilize this model effectively. The lack of management intervention inputs limits WEAM's usefulness for field or short-period erosion estimates. It does express the regional or continental impacts of wind erosion.

23.3.5 Revised Wind Erosion Equation

To expedite the availability of new technology, the revised wind erosion equation (RWEQ) effort was requested by Natural Resources Conservation Service national staff. The RWEQ model requires simple inputs to estimate daily, weekly, monthly, seasonal, or long-term soil loss from agricultural

lands. RWEQ has been field tested against measured transport data for a broad range of soil, field, management and climatic conditions. A physically based mass transport equation was derived by Stout (1990) for RWEQ. This equation is based on the concept that a self-balancing mechanism controls wind erosion and is the major relationship in RWEQ. RWEQ utilizes the principle that wind erosion is the result of the erosive force of the wind exceeding resisting forces from the surface. The resisting forces include the soil inherent wind erodibility, the surface roughness, the reduction in wind velocity with barriers, and the protection from flat or standing plant residues.

With the self-balancing concept, momentum is transferred from the wind to the soil surface (Owens, 1964). The equation derived by Stout (1990) is

$$\frac{Q_x}{Q_{\text{max}}} = 1 - e^{-(x/b)} \tag{23.8}$$

where

 Q_x is the mass being transported by wind at field length x, kg m⁻¹

 $Q_{\rm max}$ is the maximum transport capacity of wind over that field surface, kg $m^{\rm -1}$

x is the field length, m

b is the field length where wind attains 63.2% of Q_{max} , m

Equation 23.8 assumes if the wind speed is above threshold, the erosion process detaches and picks up soil particles at an increasing rate across a field. Equation 23.8 is a negative exponential decay curve that gives increasing transport mass as field length increases. The highest soil loss per unit area occurs immediately downwind of the nonerodible upwind boundary, assuming $Q_x = 0$ at x = 0 (Owens, 1964). While developed for transport layers close to the soil surface, Stout's (1990) basic equation was used to describe the total mass being transported between the soil surface and a height of 2 m. Equation 23.8 was modified to the form:

$$Q_x = Q_{\text{max}} (1 - e^{-(x/s)^2})$$
 (23.9)

where *s* is the inflection point where the slope of the line (Figure 23.7) changes from positive to negative.

Equation 23.9 gives a sigmoid curve where the mass being transported is zero at the upwind boundary, and then increases until the wind attains 63.2% of its capacity at field length "s" (Figure 23.7) (Fryrear and Saleh, 1996). Beyond field length "s" the rate of increase in transport mass is limited by the capacity of the wind to detach and transport additional soil. Therefore, the rate of increase in mass being transported diminishes until the maximum transport capacity has been achieved. The basic relationship between field length and transport mass in RWEQ reflects that as the quantity of material being

Wind Erosion 23-9

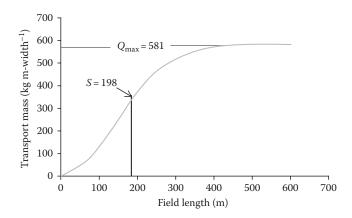

FIGURE 23.7 Measured mass flux (20 min periods, sampler 12.5 mm wide \times 50.8 mm high) from western Canada. (From Chepil, W.S., and R.A. Milne. 1941. Wind erosion of soil in relation to roughness of surface. Soil Sci. 52:417–433.)

transported approaches the maximum transport capacity of the wind, any additional material picked up must result in the deposition of a portion of the original load. The field length required for the wind to become saturated with sediment varies with the soil surface conditions and the velocity of the wind. Rarely does the atmosphere become saturated with sediment before surface conditions or wind velocity changes. With measurements of transport mass and field lengths, the coefficients $Q_{\rm max}$ and s (Figure 23.7) can be determined using nonlinear regression analysis.

The input data required to use the RWEQ model on noninstrumented fields include factors for weather (WF), soil (EF, SCF), crop (COG), and tillage (K). Measured values for the input factors were correlated with computed values for Q_{max} and s from single erosion events. These events were for fields of the same size and shape. The soil surface was flat and dry (SW = 1) with no snow cover (SD = 1).

From this analysis, the relationship between the input parameters and $Q_{\rm max}$ is described as follows:

$$Q_{\text{max}} = 109.8(WF \times EF \times SCF \times K \times COG)$$
 (23.10)

where

 $Q_{\rm max}$ is the maximum transport capacity, kg m-width⁻¹ WF is the weather factor, kg m-width⁻¹ (contains SW and SD values)

EF is the soil erodible fraction

SCF is the soil crust factor

K is the soil roughness

COG is the vegetation factor including flat residues, standing residues, and canopy

SW is the soil wetness

SD is the snow depth

The slope *s* of the empirical relationship in (8.9) is computed from the input factor using the equation:

$$s = 150.71(WF \times EF \times SCF \times K \times COG)^{-0.3711}$$
 (23.11)

where *s* is the critical field length where Q_x is 63.2% of Q_{max} , m.

When input data are available, the estimated $Q_{\rm max}$ and s values can be computed for single storms (Table 23.3). With the coefficients from Equations 23.10 and 23.11 as input for Equation 23.9, soil erosion can be computed for circular fields up to 60 ha and for square or rectangular fields up to 145 ha. The WF is time based, so erosion can be computed for any time interval when the input parameters are constant. Within the RWEQ computer program, the WF is adjusted for rainfall and snow cover and, crop residues are decomposed as a function of soil moisture and soil temperature

Wind Erosion 23-11

(Steiner et al., 1994). Soil roughness is decayed by rainfall amount and intensity (Saleh et al., 1997).

The same equation used to estimate single event soil erosion has been used with routines to adjust for rainfall, to degrade soil roughness, and to decompose crop residues to estimate erosion for the entire erosion season (Table 23.4). With the RWEQ model, erosion is computed for a field length along the dominant wind direction. The transport mass from Equation 23.9 is important in evaluating potential plant injury from blowing sand. The critical field length from Equation 23.9 can be used to plan field barrier systems or determine field widths that minimize soil erosion.

RWEQ was tested on cropland where irrigation water was removed at Reno, Nevada, and in the Northwest Coastal Zone (NWCZ) of Egypt. The presence of stones (>50 mm diameter) modifies the force of the wind. An additional subroutine is required to describe the silhouette of surface stones in the NWCZ. (The impact of surface M.M. Massif). The estimates with RWEQ were tested against field measurements for 52 erosion events at Fuka and Abu Lahu (Fryrear et al., 2008). The soil at Fuka had an erodible fraction of 0.4. The maximum measured transport mass was 738 kg m-width-1 and the estimated maximum transport was 650 kg m-width-1. The erodible fraction of the soil at Abu Lahu was 0.2, the maximum measured transport mass 262 kg m-width⁻¹, and the maximum estimated transport mass was $286\,\mathrm{kg}$ m-width⁻¹. When stones are present, the RWEQ with the stone silhouette coefficient can be used to describe wind erosion in arid regions when the small grain was seeded and harvested by hand.

23.3.6 The Wind Erosion Prediction System

As the WEQ was used limitations of its empiricism were recognized (Skidmore, 2007). The climatic factor (Woodruff and Armbrust, 1968; Skidmore, 1986) and management periods (Bondy et al., 1980) for WEQ were modified but the results were never validated with field erosion data. As erosion measuring equipment (Fryrear, 1986) and procedures (Fryrear et al., 1991) were developed, it became apparent that there were significant limitations to the empiricisms in WEQ. A concentrated effort was made to assemble new technology into a model called the Wind Erosion Prediction System (WEPS). WEPS uses a daily time step that simulates weather and field conditions to estimate wind erosion. The WEPS program includes an erosion submodel, hydrology submodel to simulate water movement within the soil and evaporation from the soil surface, a plant growth submodel to grow vegetation, a decomposition submodel to decompose residues, and a management submodel to represent tillage and other operational decisions by the land manager. WEPS is modular in design so the model can be upgraded with improved technology (Hagen, 1991). WEPS is a very complex model requiring numerous input data (Hagen et al., 1999). To illustrate some of the input requirements, the coefficients for the WEPS erosion submodel are as follows:

$C_{\rm ani}$	Coefficient of abrasion
$C_{\rm bk}$	Coefficient of breakage of saltation/creep
$C_{ m dp}$	Coefficient of deposition of suspension size
$C_{ m en}$	Coefficient of emission
$C_{\rm i}$	Coefficient of plant interception
C_{m}	Coefficient of mixing at soil surface
$C_{\rm s}$	Saltation transport parameter
$C_{\rm t}$	Coefficient of surface trapping
$F_{ m ani}$	Mass fraction of saltation impacting clods and crust
G_{an}	Vertical flux from abrasion of surface clods and crust
G_{en}	Vertical flux from emission of loose aggregates
$G_{ m tp}$	Vertical flux from trapping of saltation/creep aggregates
Gss _{an}	Vertical flux from suspension-size aggregates created by abrasion of clods and crust
Gss _{bk}	Vertical flux of suspension-size aggregates created by breakage of saltation/creep
Gss _{dp}	Vertical flux (deposition) of suspension-size aggregates above a non-eroding surface
GSS_{en}	Vertical emission flux of loose suspension-size aggregates
I_1, I_2	Least and greatest input values, respectively used in the sensitivity analysis
I_{12}	The average of I_1 and I_2
O_1O_2	Output values for I_1 and I_2 respectively in sensitivity analysis
O_{12}	The average of O ₁ and O ₂
Q	Horizontal saltation/creep discharge
$q_{\rm cp}$	Transport capacity of the surface, when 40% or more is removed
$q_{ m en}$	Transport capacity of saltation/creep
$q_{\rm s}$	Horizontal discharge of primary (nonbreakable) sand particles
qss	Horizontal discharge of suspension component
qss _o	Maximum value of qss entering deposition region
Sfer	Soil mass fraction of loose, erodible size, less than about 2.0 mm diameter at soil surface
Sfss	Soil mass fraction of loose, suspension size less than about 0.1 mm diameter at soil surface
SFss _{an}	Mass fraction of suspension size (<0.10 mm) of total (<2.0 mm diameter) created by abrasion
SFss _{en}	Mass fraction of suspension size (<0.10 mm) emitted from loose aggregates (<2.0 mm diameter)
U_*	Friction velocity
$U_{*_{t}}$	Dynamic threshold friction velocity
X	Downwind distance from non-erodible boundary

The initial soil input conditions when using the WEPS erosion submodel (Hagen, 2008) for bare aggregated or crusted soils void of residue cover include the following:

Intrinsic soil properties

Sand
Silt
Clay
Rock volume
1.5 mPa water content
Top soil layer depth

Temporal soil clod parameters

Geometric mean diameter Geometric standard deviation Maximum diameter Minimum diameter Dry stability Density

Temporal crust properties

Crust depth
Crust density
Crust cover
Crust loose cover
Crust loose cover mass
Crust dry stability

Temporal surface roughness

Random roughness Ridge height Ridge spacing Ridge orientation

Biomass cover

Flat residues

Field length

Strip Small size Medium size Large size

When WEPS (Hagen, 2008) estimates changes in soil surface conditions during wind erosion events the following surface conditions are updated:

SM_{los}	Soil mobile mass on crusted surface
$SF_{\rm cr}$	Soil fraction of surface crust cover
SF_{los}	Soil fraction loose cover on crust
$SZ_{\rm cr}$	Soil depth of crust (consolidated zone)
$SM_{ m aglos}$	Soil mobile mass on aggregated surface
SF84	Soil mass fraction <0.84 mm on aggregated surface and mobile cover fraction on aggregated surface
SF200	Soil mass fraction <2.00 mm on aggregated surface
SF10	Soil mass fraction < 0.1 mm on aggregated surface
$SV_{\rm roc}$	Soil volume rock >2.0 mm diameter
$SZ_{\rm rg}$	Ridge height
SL_{rr}	Random roughness height (standard deviation)

Additional databases are required for climate, management, and crop and deposition to supply information for the hydrology, management, crop, decomposition and weather submodels. Because of WEPS modular design, new features can be incorporated.

The WEPS erosion submodel was tested against 46 single event storms from six states (Hagen, 2004). The WEPS model under-predicted soil loss, particularly for some of the largest

events with daily weather data inputs of wind speed, wind direction, solar radiation, relative humidity, air temperature, and rainfall. Temporal field data includes surface soil roughness, plant/residue cover, and dry aggregate size distribution. The possible causes for the under prediction were essential WEPS model inputs were not measured and weathering and prior erosion may have increased soil erodibility.

The WEPS model simulation may begin at any time and may cover any period of time. Heterogeneous regions are simulated by dividing into homogenous subregions where soil type, biomass, and management are similar (Hagen et al., 1995). WEPS permits sub-hourly estimates of soil movement and describes changes in soil surface conditions during erosion events.

Wind erosion scientists must also be aware that using a model that has not been verified with field measurements can give misleading results. Estimates of wind erosion using the WEPS erosion submodel (Wind Erosion Prediction System) in the Pacific Northwest (Feng and Sharratt, 2007) did not correspond with WEG (Wind Erodibility Group) values assigned by NRCS. The general grouping of soil erodibility in the USDA SSURGO database may not hold under all management and climatic conditions.

23.3.7 Wind Erosion on European Light Soils

The Wind Erosion on European Light Soils (WEELS) model consists of modular components of wind, wind erosivity, soil moisture, soil erodibility, soil roughness, and land use. The first two components describe the temporal variations of climatic erosivity. The last four components predict the temporal soil and vegetation cover. The first version was limited to sandy soil because of the simplified parameterizations of the soil water budget. Future improvements in WEELS will include estimation of dust emission and expansion to other soils (Bohner et al., 2003).

23.4 Wind Erosion Measuring Systems: Field Sampling Instrumentation

Humans have lived with the hazards of wind erosion for millennia. Efforts to accurately measure wind erosion from natural erosion events span almost 70 years. To determine the effectiveness of control systems, methods of measuring wind erosion in the field must be available. Laboratory wind tunnel erosion samplers have been developed, but they were not suitable for field studies because some required external power, some were difficult to construct and maintain, and some lacked the capacity or efficiency for field use.

Permanent elevation pins have been used to provide a rough estimate of accumulated erosion over many years (Gibbons et al., 1983). For extremely severe events, the depth of crop roots exposed is an indicator of the depth of soil removed. To provide more detailed information on the wind erosion process, more precise field sampling equipment is required.

A field sampler was used but not described in 1939 (Chepil and Milne, 1939). A vertical slot sampler designed by Bagnold (1941)

Wind Erosion 23-13

was the first described instrument for collecting wind-eroded sand in the field, but it did not rotate as wind direction changed. Bagnold's sampler was modified by Chepil (1957) to rotate, but Chepil's sampler was not vented nor suited for highly erodible soils. A single pipe with a vertical slot was described and used because it was simple and cheap to construct and suitable for short-term monitoring of aeolian transport (Leatherman, 1978). Later samplers were vented and rotated into the wind (Fryberger et al., 1979; Merva and Peterson, 1983). These samplers had a metal edge that slid over the eroding soil surface presenting a problem in collecting surface creep.

A glass or plastic bottle with an inlet and outlet tube was designed by Wilson and Cooke (1980). These samplers are now called the Modified Wilson and Cooke (MWAC) and are easy to construct and many can be mounted on a single pole. The MWAC was slightly modified so the bottle was in a horizontal position. When tested with 132–287 micron material the efficiency was between 90% and 120% for wind velocities of 6.6–14.4 m s⁻¹ (Goossens et al., 2000).

The Suspended Sediment Trap (SUSTRA) was designed to trap airborne dust, but can be used to trap sand and soil as well (Janssen and Tetzlaff, 1991). The sand laden air enters the instrument via a horizontal metal tube 50 mm in diameter and rebounds onto a metal plate inside a central vertical pipe. The sand grains settle onto an electronic balance under the pipe. The balance is in a metal box buried in the ground and the inlet tube is 23 cm above the soil surface. The efficiencies were somewhat lower for the finest-grain sand and for winds above 11 m s⁻¹ (Goossens et al., 2000; Kuntze et al., 2000).

A wedge-shape metal sedimentation chamber (POLCA) was developed in 1995 (Pollet, 1995). The sampler chamber is 100 mm long and 100 mm (front side) and 210 mm on the back with a rectangular inlet. The sides diverge at 28.2° at both sides of the collector. Air discharges from the chamber through a 10 mm-high and 120 mm-wide screened outlet at the rear. The efficiency was between 80% and 120% (Goossens et al., 2000).

Fryrear (1986) developed the BSNE (Big Spring Number Eight) sampler that collects airborne material above the soil surface. The BSNE does not contact the soil surface and is the first field wind-aspirated sampler to accurately sample eroded material. Extensive field wind erosion data have been collected from these samplers (Fryrear et al., 1991). Wind-eroded material can be collected from a height of 0.05 m to any accessible height. The BSNE's sampling efficiency averaged over 89% for washed sand or sieved soil (sieved to remove all aggregates larger than 250 mm) and wind velocities of 10.4-15.7 m s⁻¹ (Fryrear, 1986). The same sampling efficiencies were obtained by Goossen in 2000. For particles less than $10\,\mu m$, the efficiency was 40% (Shao et al., 1993). Samples from field erosion equipment can be used to identify nutrient losses, to validate wind erosion models, and to test assumptions on the wind erosion process (Fryrear et al., 1991; Fryrear and Saleh, 1993).

Stout and Fryrear (1989) developed a surface creep and saltation sampler for collecting eroded material from the soil surface to a height of 0.2 m. Stout's sampler has an efficiency of 98% in

wind tunnel tests with fine sand and the rotating portion does not contact the soil surface. The sampler is suited for field use and has operated successfully in extremely erodible soil; however, the sampler must be lowered as the soil surface erodes. The combination of the BSNE and Stout's sampler permits the measurement of eroding material from the soil surface to any accessible height. For most studies, the BSNE samplers are located from 0.05 to 1.0 m above the soil surface.

With the development of good field erosion measurement (Fryrear, 1986; Fryrear et al., 1991), significant improvements have been made in describing wind erosion mechanics (Vories and Fryrear, 1991). Procedures have been developed to analyze measured erosion in numerous fields (ranging from 2.5) to 145 ha) to test a working wind erosion model on a variety of weather, crop, soil, and farming systems. With the measurements of field erosion, it is possible to establish baseline conditions for future comparisons. Field measurements with the BSNE (Table 23.4) and 5 min data on wind velocities verified that soil mass transport varies as the cube of the wind velocity. Mass transport increases with field length until the wind stream becomes saturated. Mass transport as high as 1231 kg m-width⁻¹ has been measured from a single erosion event (Table 23.3 Elkhart, Kansas March 9, 1992). This level of transport is sufficient to destroy most crop seedlings within 15 min. Measured soil losses from an entire erosion season varied from 0.00 to 28.9 kg m⁻² (Table 23.4).

23.4.1 Air Quality Monitoring

Most of the dust and sand sampling instrumentation described above was designed to collect a sample of the eroded material within the saltation/creep zone. While some suspended material may be collected, the efficiency of all the samplers decreases with grain sizes below 100 microns. A PM₁₀ sampler must be tested according to procedures and performance specifications set by the U.S. Environmental Protection Agency. The sampler must be tested in a wind tunnel to show a 10 \pm 0.5 micron cut point in aerodynamic diameter for each wind speed of 2, 8, and 24 km h-1. The Kimota 180 and the Wedding ambient beta gauge PM₁₀ samplers were tested against an Anderson SA 1200 high-volume sampler (Tsai et al., 1996). The Kimoto 180 significantly underestimated PM₁₀ because the cut point of its inlet is 3.5 microns. Deviations ranging from 0% to 50% were measured and increased with water vapor content. The daily average PM₁₀ concentrations of the Wedding were 7.2%–9.3% lower than the SA 1200. To collect samples of material smaller than 50 microns requires instrumentation with a calibrated and controlled vacuum pump. The Partisol Dichotomous Aerosol Air Sampler (Model 2025) may be used in conjunction with wind speed and direction sensors, data logger, and a source of power to collect filters with 2.5 and 10 micron particles. To collect a sample of 10 micron material the TSI Dust Trac aerosol monitor may be used if power is available. These instruments are expensive and collect data at only one height unless multiple units are used.

23.4.2 Threshold Velocities

Visual observations can be used to identify when soils begin to erode, but it is not always possible to be in the field when erosion begins. Gillette and Stockton (1986) developed a piezoelectric quartz crystal sensor to detect the exact minute soil movement begins. With this device, the number of particles and the momentum of the particles being transported by the wind can be measured. This sensor, called SENSIT, also permits the researcher to accurately determine the start and duration of wind erosion events and the intensity of blowing sand during the erosion event. Coupled with wind direction sensors, the direction of erosive winds can be determined. A similar device called the Saltiphone was developed to determine when soil movement begins and to obtain a relative measure of sand flux (Spaan and van den Abele, 1991). Depending on soil texture these sensors can be very useful in measuring threshold velocities and mass transport.

23.5 Major Control Systems

The resources available influence the type of practices used to control wind erosion. The major wind erosion control practices include manipulation of surface residues, soil roughening, planting, wind barrier/shelterbelts, and the use of cover crops and soil amendments. No single wind erosion control practice is equally suited for all regions of the country because the climate and management options are so variable. The recommendations are to understand the principles of erosion control practices and use combinations of practices. For example, surface residues can be very effective, except in the more arid climates where normal residue levels may not be sufficient to provide complete protection. Also, in some regions termites may consume all dead surface residues. Soil roughening may be effective until rainfall or irrigation has destroyed surface aggregates. Wind barriers or shelterbelts can provide excellent protection, but like soil ridges they are not effective when the wind is parallel to the barrier. Trees require many years before they are tall or dense enough to provide complete protection from perpendicular winds. In the Fuka area of the Northwest Coastal Zone of Egypt, tillage perpendicular to the erosive wind constitutes an effective wind erosion control practice. It is highly recommended because the local Bedouins favor soil conservation methods that are low cost, simple to implement, and rely on local resources and skills (Wassif et al., 1999).

23.5.1 Crop Residues

The effectiveness of crop residues in controlling soil erosion can be expressed as a percentage of the soil surface that is covered. After small grains, corn, or sorghum are harvested, there is usually sufficient residue in the field to protect the soil. When these same residues have value as fodder for animals, fuel (Williams and Balling, 1996), or building materials, there are economic pressures to remove more and more of the residue.

The relationship between soil erosion and soil covered with residues flat on the soil surface illustrate that covering even 30% of the surface reduces soil losses by 70% (Figure 23.4). The challenge is to leave sufficient residue in the field to maintain the soil resource.

The impact of standing stubble has been extensively researched (Englehorn et al., 1952; Siddoway et al., 1965; Skidmore et al., 1966). van de Ven et al. (1989) developed a silhouette index to describe the relationship between standing plant material (stubble) and wind erosion (Figure 23.5). This way of describing the effect of standing residue is currently used in the RWEQ wind erosion model. Standing residues present a silhouette to the wind that reduces the wind stress at the soil surface. Standing residues are about six times more effective in reducing wind erosion than the same mass lying flat on the soil surface (Figure 23.6). The combined effect of crop residues and soil roughness can be expressed as the product of the coefficients (Horning et al., 1996).

As seedlings develop and mature, the taller plants provide some protection to the soil surface. This protection has been related to the portion of the soil surface covered with plant canopy (Bilbro et al., 1994; Armbrust and Bilbro, 1997). As relationships that include rigidity, leafiness, and canopy height are improved, these will be incorporated into the new models.

23.5.2 Soil Roughness

Managing crop residues is an important method of controlling wind erosion but if crops other than small grains, corn, or sorghum are grown, residue production may not be sufficient to protect fragile soils. During drought periods or when residue levels are not adequate to protect erodible soils, other erosion control methods must be employed.

Roughening the soil with tillage implements can be an effective alternative depending on soil texture of the soil surface (Chepil et al., 1963a; Fryrear, 1984) (Figure 23.3). The impact of effective tillage operations was described by Chepil and Woodruff (1954). They reported soil losses of 25 Mg ha⁻¹ were reduced to 0.25 Mg ha⁻¹ with a single listing operation. The same magnitude was reported by Fryrear (1969). Soil roughening is most effective when performed perpendicular to the erosive wind and before the soils begin to erode (Woodruff et al., 1957). Timing is critical, and may be more important than the implement used to roughen the soil (Chepil et al., 1952; Woodruff and Chepil, 1956).

Since tillage can be effective in controlling wind erosion, methods of describing soil roughness (Zobeck and Onstad, 1987; Potter and Zobeck, 1990), tillage effects (Zobeck and Popham, 1992; Saleh et al., 1997) and methods of measuring surface roughness (Zobeck and Onstad, 1987; Saleh, 1993) have been developed.

23.5.3 Wind Barriers/Shelterbelts

Hedges (McDonald, 1971), trees (Woodruff and Zingg, 1955; Woodruff, 1956a), and annual crops (Fryrear, 1963) have been used as barriers to reduce wind speeds to the lee of the barrier. In general wind barriers protect the soil surface 10 times the height

Wind Erosion 23-15

of the barrier. However, the precise length of protection offered by a barrier depends on wind speed, barrier density, and surface condition. Field research is underway to develop a wind barrier model that relates leeward wind reduction and the shape and extent of the protected zone to wind velocity and barrier density (J.D. Bilbro, Personal communication). The efficiency of a shelterbelt to control shifting sand is governed by the height, width, and porosity of the trees (Draz and Zaghioul, 2007). Bilbro and Stout (1999) studied the effect of uniform plastic pipe barriers on wind patterns in the field, and found that a barrier with 12.5% optical density would reduce downwind velocities over a 30 m distance by 4.3%. Increasing the number of pipes to achieve 75% optical density reduced wind velocities over the same field by 32.5%. Multiple rows of "pipe barriers" were also tested and equations developed to establish relationships among wind barrier conformation, barrier density, number of rows, and wind velocities. Wind tunnel studies of models of multi-row wind barriers showed that the optical density of the first row on the windward side of the barrier system was most important in defining the effectiveness of the barrier system (Fryrear et al., 2000), but normally the protected zone for the barrier is measured from the leeward row. Wind barriers can be very effective in controlling wind erosion in higher rainfall regions, but in limited rainfall areas or areas without winter snowfall, perennial barriers extract essentially all the soil water for a distance of three times the barrier height on both sides of the barrier (Bilbro and Stout, 1999).

23.5.4 Soil Amendments

Economical control of wind erosion usually requires the use of the available soil and plant resources. In many regions wind erosion is closely associated with drought conditions. During prolonged droughts plant residue levels decline and soil roughness techniques are ineffective. If the drought continues over multiple years, annual crop barriers may not grow and trees may die. The options available for reducing wind erosion become very limited. To provide one additional option, research has been and is being conducted on soil amendments (Chepil, 1954b, 1955; Chepil et al., 1963b; Lyles et al., 1969; Armbrust and Dickerson, 1971). The problems include cost of the amendment; excessive quantities needed, and limited effectiveness.

23.6 Conclusions

Wind erosion is one of the basic geological processes that shape and mold the landscape. Deep deposits of rich loess soil are evidence that wind erosion and deposition have played a major role in modifying the earth's surface. These loess soils are vital agricultural regions in modern agriculture.

Research on wind erosion began in the 1700s and continues today. This research is aimed at understanding the mechanics of wind erosion, measuring the products of erosion, modeling the processes, and understanding interactions. Field measuring methods have been developed to describe plant residues and soil roughness conditions.

Modeling wind erosion in the United States began with WEQ. New models (WEAM, TEAM, RWEQ, WEPS, and WEELS) are much more flexible and reflect new science not available in WEQ. These models represent the current knowledge of wind erosion mechanics and provide the cornerstone for evaluating wind erosion control systems. These systems take advantage of the available soil, plant, management, and weather resources. When used to plan management systems, the wind erosion model must make accurate estimates for extended periods of time and not just for single events. Therefore, it is imperative that models be field tested and validated over many months or multiple years. Also, when a model is used beyond its original scope the user must be aware of the mechanics and limitations of the model.

Field measuring techniques have progressed to the point where it is possible to detect the moment soil erosion begins and mass is being transported. With these field samples the vertical and horizontal distribution of eroded material within an eroding field can be described. These field data permit the verification of estimated erosion.

The new models permit designing systems that effectively utilize the available resources and efficiently control wind erosion. This does not mean that erosion will no longer be a problem, because wind erosion is a basic geomorphologic process.

24.1 A Brief History and Overview of Land Application

Before the introduction and widespread use of commercial fertilizers in the early twentieth century, application of manures and other by-products to soils was an important way of maintaining soil fertility and productivity. These applications were made based on the empirical observation that plant growth was stimulated by such applications. The importance of these materials in agricultural production declined during the twentieth century in response to the lower cost of commercial (inorganic) fertilizer per mass of nutrient applied and the concentration of animals in confined animal feeding operations (CAFOs) removed from the farm. The term "waste" was applied to manures and other materials, since these materials were considered to have a negative (i.e., disposal) value in lieu of their use as soil amendments. However, increasing energy costs have recently caused dramatic increases in the cost of commercial fertilizers, especially N fertilizers. In addition, global reserves of phosphate rock are dwindling. At current rates of extraction, known United States reserves will be depleted in 40 years and known global reserves in about 90 years (Vaccari, 2009). This, coupled with current environmental regulations regarding release of nutrients into the environment and the rising costs associated with construction of landfills, has revived interest in land application of waste materials to crop and forest lands as a way of avoiding disposal costs while recycling nutrients to soils. The organic material present in many of these by-products also has the potential to build humus levels in soils and thereby improve long-term productivity.

A wide range of materials derived from both agricultural and industrial activities have been proposed for land application. From the point of view of the producer of these materials, they are wastes if they have no or negative value. If they can be shown to have positive growth effects on cultivated plants that justify their land application, and do not have adverse environmental impacts with such a use, a better term may be by-products rather than wastes (Powers, 1998). The focus of current research is to provide guidelines for the environmentally safe use of such materials in agriculture as substitutes for commercial fertilizers and to avoid the cost of landfilling of a potential resource.

24.1.1 Historical Perspective

The oldest stable agricultural systems known, in both the West and East, employed additions of organic matter, primarily animal manures and nightsoil (human excrement), to soil to maintain productivity. Asian agriculture dating from 2500 BCE employed these materials extensively. At about the same time, Greek and later Roman agriculture used manures as well, but did not find human waste as suitable, perhaps due to its tendency to cause disease (Tisdale et al., 1993).

During the Middle Ages, agriculture appeared to follow the Roman model, and continued use of organic materials (manure, food waste, and perhaps human excrement) over time created distinctive topsoil materials high in carbon (C) and extractable nutrients (plaggens). Similar soil horizons have been found in Amazonia at about the same time associated with village sites

of long habitation, presumably enriched with food processing wastes and charcoal added intentionally (or not) to garden plots near habitations.

Industrialization in the West during the eighteenth and nineteenth centuries brought many changes to agriculture, which had been operating in Europe and the United States with only modest change since Rome. The emphasis on tillage in order to allow plant uptake of humus continued to encourage manure additions, but Liebig's clarification of the role of soil-derived nutrients in the 1860s opened the way to widespread use of fertilizers for their nutrient, rather than their humus content.

Prior to the development of industrial processes to manufacture inorganic fertilizers in the later nineteenth century, imported guano (sea bird manure) from Chile and the Pacific islands was a major fertilizer used in row crop production in Europe, and particularly in the southern United States for cotton production as an N source and a P source (Wines, 1985). Once the Haber process was developed to manufacture ammoniacal salts on an industrial scale, and phosphatic mineral deposits were discovered and mined along the eastern seaboard and Florida, the rapidly depleting guano reserves were abandoned.

During the period 1920–1940, inexpensive supplies of inorganic nutrients coupled with other changes greatly increased yields of crops and encouraged specialization in farming, which often meant separation of row crop and animal production. In confined production facilities, manures became wastes, and an increasing disposal problem arose. While much of the focus in the 1970s was on point source pollution (i.e., on industrial and municipal discharges), by the 1990s it had become clear that stockpiled or overapplied manures were a major contributor to nonpoint source N and P pollution of surface and groundwater.

The environmental movement of the 1970s initiated the modern emphasis on environmental quality and recycling, which, coupled with economic constraints on producers of a variety of by-product materials, has led to a new focus on utilization of a wide range of these materials on agricultural lands.

24.1.2 Types of By-Products Considered

Animal manures, largely from cattle, poultry, and swine production, still make up the bulk of by-product materials applied to soils. The increasing centralization and industrialization of animal production has led to problems with distribution of such manures back to cropland, primarily due to high transport cost relative to cost of equivalent inorganic nutrients. Despite the long history of use, rates of application are currently being studied to determine water quality impacts and optimal application rates for crop production.

Domestic waste, the nightsoil of preindustrial days, is now handled in wastewater treatment plants. The treated solids are separated from the wastewater. When municipal sewage solids (sewage sludge) are treated and meet standards so that they are suitable for land application, they are known as biosolids. This material is increasingly land applied, either in dedicated land-treatment facilities or on farmers' fields. Governmental regulation is encouraging application to land through publication of guidelines for acceptable nutrient and heavy metal loadings, thereby avoiding landfilling of this material. Other domestic wastes include yard trimmings (grass clippings, chipped limbs, etc.), now commonly composted or mixed with other by-products instead of consuming landfill space.

Industrial by-products are increasingly being viewed as potential soil amendments due to their negative value to industries and their capacity to substitute for costly inorganic fertilizers. Some industrial by-products such as blast furnace slags, wood ash, and kiln dusts have been used locally as lime substitutes due to their alkaline nature; metal refining baghouse dusts are commonly used to formulate micronutrient fertilizers. Other materials such as coal fly ash, by-product gypsums, food processing, and pulp and paper manufacturing by-products are being considered for land application based on either alkalinity, nutrient content, and/or organic matter content. With these new materials, there is a greater uncertainty concerning possible environmental hazards from trace metal and organic contaminants, and this has prompted ongoing research.

The Resource Conservation and Recovery Act (RCRA) and the Clean Water Act (CWA) and subsequent USEPA rulings contain regulations governing the definitions of waste types, discharge or loading limits for pollutants, and management practices for land application of biosolids (Walker et al., 1997). In particular, hazardous waste is defined as materials that are corrosive, ignitable or explosive, or toxic, the latter based on the leaching potential of trace metals. While under certain circumstances materials defined as hazardous may be land applied, in general, these materials cannot be used as soil amendments.

24.1.3 Rationale for Land Application

Land application in the sense used here refers to addition of by-products to soil for the purposes of improving crop growth, either through addition of nutrients or improvement of soil physical or chemical properties, either in the short or long term. Materials used for land application should be studied and documented to be effective for use in agriculture while posing no threat to the environment. This is distinctly different from land treatment, which suggests that materials are being applied to land primarily in order to dispose of (treat) them. There is a long history of land treatment of waste materials such as biosolids, secondary municipal waste water, and industrial solids and waste waters on dedicated treatment facilities, which are managed and monitored for such uses. The design and operation of such facilities are typically under permit from governmental regulatory agencies, and are not discussed in this review.

The key to land application is the idea of beneficial reuse, which is the major criterion used by the USEPA and many state environmental agencies to consider materials for land application. Animal manures typically have not been closely scrutinized due to their long history of use and accepted value in agriculture, although increasing use of hormones and high metal levels as feed additives has raised some questions regarding

environmental safety. Other materials, however, require testing to document the absence of significant levels of contaminants, and to demonstrate some positive effect on crop yield or potential soil productivity. This latter criterion may be addressed by demonstrating improvement in long-term productive potential by increasing soil water-holding capacity, improving soil structure or tilth, or by overall increase in nutrient levels that may not affect yield immediately.

The United States and the European Union (EU) have taken different regulatory approaches to determining if by-products can be land applied. The USEPA uses risk assessment to determine acceptable concentrations of potential contaminants. In 1993, USEPA promulgated 40 CFR Part 503 as the standards for land application of municipal biosolids. Part 503 specifies the degree of treatment for organic material stabilization and pathogen reduction as well as acceptable concentrations and annual and cumulative loadings for nine contaminant metals applied to crop land (USEPA, 1993a, 1993b). While this ruling has been applied to other types of by-products, it is not clear how the specifications apply to other types of wastes. Regarding animal manures, a growing emphasis on comprehensive nutrient management plans (CNMP) in the United States has had a significant impact on addressing issues of nutrient export from fields due to over- or mis-application.

Despite these successes, questions have increasingly been raised regarding the overall safety of land application programs, particularly the risk assessment approach used by EPA, both in its general outline and specifics of the data used in the models (Harrison et al., 1999; National Research Council, 2002). Public opposition to land application of by-products, particularly biosolids, has escalated over the past 10 years, evidenced by a citizen petition to ban biosolids application nationally in the United States (Center for Food Safety, 2003; the petition was denied by EPA) and numerous critical, even vitriolic web sites on the topic (displayed by any Internet search of "sewage sludge"). The range of criticisms includes regulatory incompetence, collusion of regulators with industry, and the failure of research to prove the safety of land-applied products. Biosolids are increasingly portrayed in the media as a "hazardous" or "toxic" waste, lumped with industrial by-products that have occasionally been misapplied to soils and resulted in serious contamination (e.g., Wilson, 1997). Using Beecher et al.'s (2005) terminology, the public's "perceived risk" with respect to biosolids has grown, regardless of the "actual risk." It is likely that EPA will need to account for such perceptions if land application programs are to be "sustainable" in the United States, a process that will involve engaging stakeholder groups in project planning, management, and in research (Bastian, 2005).

The EU has adopted much more stringent standards regarding land application of wastes than those of the United States. This may be due to Europeans' longer view of history and hence resource conservation (Harrison et al., 1999), or to an adherence to some form of the "precautionary principle," which states that scientific uncertainty shall not be used to justify action (or inaction) that might result in severe or irreversible environmental

harm (Goldstein, 2004). This idea can be applied to many environmental questions where lack of "complete" scientific understanding limits our confidence in regulating the environment. The European ban on genetically modified crops and use of hormone treatment of food animals are examples, and illustrate that in the absence of "certainty" of safety, "public perception of the potential for harm is sufficient to ban a food or chemical with little if any need for scientific data" (Goldstein, 2004, p. 490). Such an approach is the antithesis of risk assessment, dose–response relationships, and modern environmental and toxicological science. The evolution of environmental regulation of land application in the United States will depend on the interplay of these different approaches.

24.2 Properties of Common Land-Applied By-Products

24.2.1 Agricultural Materials

Strictly speaking, the single most important type of agricultural by-product applied to soils is crop residues. However, crop residues are not often classified as a waste material because they are naturally returned to the soil during the course of tillage operations, and because it is universally acknowledged that returning residues to the soil enhances soil productivity. Therefore, crop residues will not be discussed further in this chapter.

By virtually any standard the most important agricultural by-products applied to soils are animal manures. Because of the amounts applied and their relatively high nutrient content, it could even be argued that agricultural animal manure is the single most important land-applied by-product of agricultural or nonagricultural origin. Huge quantities of agricultural animal manures are produced each year in the United States and throughout the developed countries of the world. In 1978, a USDA task force estimated that just over 0.5 billion Mg (fresh wt.) of manure, or 39% of all the agricultural animal manure generated in the United States, was produced in confined areas and was thus available for land application. Brady and Weil (1996) estimate that over 1 billion Mg (fresh wt.) of animal manure is now produced annually in confined livestock and poultry operations in the United States.

The geographic distribution of animal manure production in the United States, as well as total quantities produced, has changed markedly since the middle of this century. Prior to the 1940s, animals and crops were for the most part raised together on millions of small farms scattered throughout the world. In this precommercial fertilizer era, manure was a valuable resource. It was faithfully collected, stored, and applied to crop land at rates that seldom supplied nutrients in excess of crop needs, primarily because there was an appropriate balance between the number of animals produced and the amount of land available. With the advent of chemical fertilizers, manure was no longer seen as an economical source of plant nutrients, so small farmers divested themselves of their livestock. Corn, wheat, and sorghum that were produced inexpensively using the new chemical fertilizers

became an economical source of feed grains for a new form of animal agriculture that was characterized by economy of scale, high density, confined production and centralized processing and distributing facilities. Higher land prices, increased cost of labor and other factors have prompted animal production facilities to locate in areas not well suited to row crop agriculture. The end result is a concentration of animals in specific regions of the country where limited areas of crop land cannot accommodate the quantities of manure produced. The situation is exemplified by the poultry industry in the southeastern United States (AR, AL, GA, NC, DE, MD) where intensive poultry production generates more manure than the local region's crop lands and pastures can accommodate.

The chemical and physical properties of the manures produced by today's animal agriculture vary widely. A property of particular importance as far as storage and handling of manure is concerned is water content (or, conversely, solids content), which is sometimes referred to as consistency. Manures containing less than 5% solids are considered liquids, while those containing between 5% and 12% solids are referred to as slurries; those containing between 12% and 20% solids are semisolid; and those containing more than 20% solids are solids. When they are first excreted, many agricultural animal manures are classed as semisolids. Liquid manures and manure slurries typically are produced when water is used to wash semisolid manures out of the animal rearing areas into pits or lagoons for storage. Left undisturbed in a lagoon, solids will settle out, creating a situation in which manure slurry is overlain by liquid manure. Solid manures are produced either by drying of slurries or semisolids, or by mixing of manures with a carbonaceous bedding material such as straw or wood chips. An example is chicken broiler litter, which is a physical mixture of poultry (broiler) manure and either rice hulls, wood chips or sawdust.

The chemical composition of animal manure is highly variable and depends on many factors including (1) type of animal, (2) nature and composition of feed, (3) nature and composition of added bedding material, (4) manure/bedding ratio, and (5) the manner in which the manure was collected, stored, and handled prior to land application (Sutton, 1994; Wright et al., 1998). Representative chemical composition data for a number of different types of animal manures are presented in Table 24.1. Poultry and swine manures generally have higher N and P contents than either beef or dairy manure. In addition, poultry litters tend to have lower N and P contents than poultry manures because of the diluting effect of the carbonaceous bedding materials present in litters. These data also illustrate the fact that when animal manures are applied to soil, significant quantities of nutrients other than N and P are added to the soil. For example, application of 4 Mg ha⁻¹ (dry wt.) of swine manure having a composition similar to that shown in Table 24.1 would provide, in addition (kg ha⁻¹) to 252 N and 80 P, 100 K, 180 Ca, 40 Mg, 4.4 Fe, 1.56 Zn, and 0.6 Cu. It should also be noted that because of the high C content of manures, one of the major benefits of adding animal manures to soil is the resulting increase in soil organic matter (SOM), which exerts a beneficial influence on

so many soil physical properties, such as water infiltration rate, aggregate stability, aeration and so on.

It should be emphasized that the data in Table 24.1, while representative of actual analyses, are for comparative purposes and should not be used to calculate actual manure application rates. The variability in the chemical makeup of manures is so high that the use of average data to calculate manure application rates can result in significant over or under application of nutrients (Mullins et al., 2005; Kleinman et al., 2005). In actual practice, a sample of the manure to be land applied should be analyzed to determine its exact chemical composition, which should be used in application rate calculations. Sims (1995) has discussed both the need for and problems associated with obtaining accurate chemical analyses of agricultural animal manures.

24.2.2 Forestry Products

Processing of forest products generates large amounts of by-products, most of which are currently incinerated, landfilled or stockpiled near production facilities. The production of pulp for papermaking is the major regional source of by-products, with industries concentrated in the Southeast (AL, GA, SC, TN), New England (MA, NY, PA), and Pacific Northwest (WA, OR). Total by-product production in the United States was approximately 13 million Mg (dry wt.) in 1989, but has likely declined with the reduction in domestic pulp production since 2000. About 50% of total by-products is composed of organic-based sludges and the remainder of inorganic materials such as by-product lime and boiler ash (NCASI, 1997; Unwin, 1997).

During the pulping process, alkaline dissolution of lignin is employed to separate the cellulose for further processing. The solid by-products produced consist of inorganic residues from the wood and processing chemicals (grits, dregs), reject cellulose and wood knots, spent alkali used in regenerating the pulping chemicals (lime mud), and ash from boilers fired with wood by-product and/or fossil fuel. The reject cellulose taken directly from the pulping digestor is termed primary sludge; often this material is sluiced to a lagoon and mixed with other by-product

^b Broiler litter; after Edwards and Daniel (1992) and Brady and Weil (2008).

streams (ash and alkali by-product), and may undergo some forced aerobic decomposition. This latter material is referred to as secondary or activated sludge. Pulp and paper mills use steam generated in boilers that typically burn wood by-product, bark, reject pulp and accessory fossil fuels, generating ash that is variable depending on the fuel source. A variety of proprietary processes are used in pulp and paper making, and individual plants differ substantially in their handling of by-product streams; some mills combine all by-product streams prior to disposal. Therefore, by-products are extremely heterogeneous and typically vary in composition within the same mill over time as operating conditions change.

Some general properties of the major classes of pulp and paper by-products are given in Table 24.2. Ranges are shown rather than average values, given the extreme variation in products between different mills. Both primary and secondary pulp sludges are largely composed of organic materials (reject wood and pulp), while the other classes of by-products are primarily inorganic. Nutrient contents are in general low, particularly for N, P, and K. Some ashes and the lime muds are quite alkaline (pH $_{\rm H_2O}$ > 12), and have good potential as agricultural lime substitutes. Calcium

MacKinnon (eds.) Agricultural uses of byproducts and wastes. American Chemical Society, Washington, DC; Someshwar, A.V. 1996. Wood and combination wood-fired boiler ash characterization. J. Environ. Qual. 25:962–972.

carbonate equivalences (CCE) for lime muds are often >90%, and in the range 10%–65% for primary sludges, which often contain free CaCO₃ (Morris et al., 1997).

Trace element contents, including regulated metals such as Hg, Cd, and As, are quite variable but typically quite low in most of these materials. Ash from boilers using nonwood fuel (coal, shredded tires, oil) are not reported here, but are often higher in trace elements such as As and Zn. Dioxin content of ash and pulp by-product from mills where Cl₂ process bleaching is used has been a subject of concern. Studies have shown significant levels of dioxin or furan compounds in some bleached kraft mills where Cl₂ bleaching is used, but this method is rapidly being replaced by other technologies (Camberato et al., 1997; Miner, 1997). Older stockpiled sludges in lagoons may locally contain higher levels of dioxins and furans. Except where salt laden (i.e., salt water-saturated) wood was used as a feedstock, boiler ash from pulp and paper mills is quite low in these compounds (Someshwar, 1996).

Land-applied forestry by-products are used principally as liming agents, fertilizers, soil conditioners, and mulches.

24.2.3 Industrial By-Products

There is obviously a large range of by-product materials produced by industries, some of which may have potential for use as soil amendments. Many have no appreciable nutrient, organic or alkali content that might benefit crop production, or have levels of toxic contaminants that rule out land application. Several classes of by-products described in this section have been used, or have been suggested for use on soils. Several types have been tested for crop response or agronomic efficacy or for potential environmental impacts, but certainly much work remains to be done in this area. The use of any of these materials is not recommended in the absence of careful chemical characterization and consultation with agricultural and environmental experts or state officials.

24.2.3.1 Slags

Iron and steel making slags are perhaps the best known industrial by-products historically used in agriculture. These materials are produced by addition of lime to furnaces to remove Si impurities, and are composed primarily of CaSiO₃. Blast furnace (Fe) slags have high CCE values (80%–100%), and have been used for many years locally as lime substitutes in the northeastern United States and Europe. Basic (steel) slags are produced from high P ores, and have a high P content (4%–8%) as well as considerable CCE (40%–60%; Tisdale et al., 1993). Electric furnace slags have intermediate CCE and P values.

In 1995, 21 million Mg of slag were produced in the United States, with about 60% being Fe slags and 40% steel or electric furnace slag (USGS, 1997). In the past, much of the basic slag was land applied as a P source (10 million Mg in 1974), but current use is low, with only 0.25 million Mg land applied worldwide in 1995. In the United States, production is centralized in the industrial Midwestern states (IL, IN, OH, PA), and competing

^a Mean values in parenthesis where available.

uses (cement production, lightweight aggregate) have increased prices to \$30–\$100 Mg⁻¹ (USGS, 1997), largely pricing agricultural uses out of the available market.

No environmental studies dealing with contaminant (i.e., heavy metal) contents of slags or their fate in soils appear in the literature; it is likely that certain metals alloyed in steel (Ni, Cr, Mo) may be present in the slag and should be carefully monitored in any land application.

24.2.3.2 Fly Ash

Coal-burning electric-generating plants produce fly ash in all industrial countries. In the United States in 2001, utilities produced 57 million Mg of fly ash, as well as 18 million Mg of bottom ash and boiler slag materials (Kalyoncu, 2001). Worldwide, 480 million Mg are produced, with China, India, North America, and Europe responsible for about 100 million Mg year-1 each (Feuerborn, 2005). Fly ash is a fine (typically <0.05 mm diam) largely silicious material trapped in electrostatic precipitators prior to discharge of flue gases from smoke stacks. Nationally, about 50% of this material is reused as a cement additive or used in structural fills, roadbases, mineshaft backfilling and other engineering applications; the remainder is stored on site in lagoons or landfills. While fly ash has traditionally been exempt from regulation, new landfill construction is likely to require liners and monitoring of leachates to prevent groundwater contamination with metals, which has been observed at a number of existing facilities. These higher disposal costs have spurred an interest in use of fly ash as a soil amendment.

The composition of coal fly ash differs significantly from that of wood ash (Table 24.2) due to the nature of the fuel; coal has a greater ash content due to inclusions of minerals in the coal as it was deposited and then modified over geologic time. Clay minerals deposited within the coal bearing strata give rise to high Si and Al contents, and Fe precipitated as pyrite (FeS) within the coal adds Fe and a range of associated trace metals. In the United States, coals mined in KY, IN, AL, WV, IL, and PA tend to be higher in pyrite (high S, bituminous coals), with a resulting ash that is acidic to neutral in pH, high in Fe, and relatively low in Ca and Mg, classified as Class F in the ASTM system (Mattigod et al., 1990). Ash from sub-bituminous and lignite western United States coals (low S) has lower Fe and associated metals, and higher Ca, Mg and pH values (Class C), and is more pozzolanic (hardens irreversibly, similar to portland cement), and therefore is more desirable as a cement additive. Representative chemical analyses are given in Table 24.3.

The Class F ashes, constituting about one-half of the annual production in the United States, have limited nutrient value; major nutrient concentrations are low, and studies of availability indicate that K in particular is not readily water soluble, limiting its effect as a fertilizer. These ashes typically have low CCE (1%–10%) and, therefore, have limited potential as lime substitutes. A wide range of microelements are present that have a potential benefit for agricultural use. However, some Class F ashes have As levels that are a cause for concern environmentally. Using USEPA metal limits for biosolids (Section 24.5.1)

nd = no data available.

as a comparison, As concentrations above the 75 mg kg⁻¹ ceiling occurred in about one-half of ashes in this group. In comparison, Class C ashes are much higher in Ca, Mg, and K, and have a significant liming potential due to the higher CCE values (20%–60%). Trace metals are overall lower, with only 1 sample in 9 having >75 mg kg⁻¹ As. Boron is elevated in all ashes relative to levels in soils, particularly in Class C ashes. Boron phytotoxicity may injure plants temporarily, although this effect often disappears as B is leached out of the root zone by rainfall. There are no human health effects of B in food crops or water supplies.

Finally, it should be noted that the solubility of P in high P soils (e.g., resulting from over-manuring,) has been shown to decrease following application of fly ash (Stout et al., 1998, 1999, 2000). Thus, fly ash shows promise in the remediation of high P soils.

24.2.3.3 Gypsum (CaSO₄ \cdot 2H₂O)

Gypsum is produced as a by-product by a number of industries, most notably the phosphate fertilizer industry and electric generating utilities as well as by pigment processing and electroplating industries. Nearly 1 billion Mg of phosphogypsum (PG)

from P fertilizer processing are stockpiled in Florida and the Mississippi Valley, with an annual production of 40 million Mg, mostly in central Florida (Miller and Sumner, 1997). In addition, electric utilities are producing increasing amounts of flue gas desulfurization gypsum (FDG) in scrubbers designed to remove SO₂ from stack gases in response to amendments to the Clean Air Act. About 30 million Mg were produced in 2006 in the United States from forced air scrubbers that fully oxidize SO₂ to gypsum, which is a large increase over the past 10 years (American Coal Ash Association, 2006). Other scrubbing technologies produce materials containing calcium sulfite (CaSO₃) mixed with fly ash (Korcak, 1995). Some of the gypsum produced is used in wallboard manufacture, but continued emphasis in the United States and Europe on SO₂ removal from coal-fired power plants suggests increased production in the future (Kalyoncu, 2001).

Some typical analyses for various gypsiferous by-products are given in Table 24.4. Fluidized bed combustion (FBC) material is produced from a dry scrubber that injects lime directly into the furnace, one common technology that produces a mixed by-product

Soil amendments and environmental quality. Lewis Publishers, Boca Raton, FL.

composed of calcium sulfite/sulfate material containing unreacted lime. It has a variable composition depending on the boiler design often containing considerable residual CaO or Ca(OH) $_2$ and some fly ash (evidenced by the Si content). No calcium carbonate equivalent (CCE) data were located, but it would likely be a reasonable lime substitute. PG and FDG are relatively pure materials, approaching the theoretical 23% Ca and 19% S of CaSO $_4 \cdot 2H_2O$. Impurities in PG are largely Si sand and a minor amount of fly ash in FDG. Trace elements are quite low in all materials, with B being the exception in the case of FBC and FDG materials.

Both PG and FDG have a history of use in agriculture; in the southeastern United States, by-product CaSO₄·2H₂O materials are applied to peanuts as a Ca supplement, and various types of CaSO₄·2H₂O have been used in the western United States, Australia, and South Africa on high Na soils to improve physical properties. Higher application rates (up to 10 Mg ha⁻¹) have been shown to improve root penetration on acid subsoils with no enhanced metal uptake on a range of crops (Shainberg et al., 1989; Sumner, 1993; Ritchey et al., 1995). Field studies using FDG have demonstrated limited uptake of metals over 3 years on a range of crops from 10 Mg ha-1 application rates on three soils in Georgia (Sumner et al., 1996; Miller and Sumner, 1997). The USEPA, however, has restricted the use of PG containing >10.0 pCi ²²⁶Ra g⁻¹ due to trace contamination with radionuclides of the ²³⁸U decay series, principally ²²⁶Ra and ²²²Rn gas, which carry certain health risks (Alcordo and Rechcigl, 1995; Miller and Sumner, 1997). The risk assessments on which this decision were based involve inhalation hazards to persons living on highly amended soils, and are being challenged by fertilizer and phosphate industry groups. Currently, PG containing >10 pCi g⁻¹ of total radiation is restricted and cannot be land applied.

Finally, it should be mentioned that, like fly ash, FDG application has been shown to sequester P in high P soils (Stout et al., 1999; Callahan et al., 2002).

24.2.3.4 Flue and Kiln Dusts

These are fine airborne particulates collected from manufacturing facilities, particularly metal processing/refining and cement manufacturing. Flue dusts often refer to fines from metal processing (especially electric furnaces), and are often ferrous with admixtures of heavy metals; something in the range of 5 million Mg year-1 are produced in the United States, most of which is either recycled within the facility or landfilled. If such dusts do not contain contaminant metals (Cd, Pb, etc.), they are a valuable source of trace nutrients, and significant quantities are used by the micronutrient industry as a source of Cu and Zn fertilizer (Wyatt, 1997). However, many flue dusts and similar products contain contaminant metals (up to 20% heavy metals such as Pb, Cd, and Zn) and are classified as either hazardous wastes or are derived from hazardous wastes, thus restricting their use. It should be noted that several instances of ill-informed use of flue dusts as liming materials and/or micronutrient sources have resulted in Zn and Pb poisoning of crop land to the point of near sterilization (Davis et al., 1995b), and the use of such materials should be carefully monitored for metal loading rates applied to soils.

Cement kiln dust is a fine-grained mixed calcium silicate/ oxide/carbonate material produced during kilning of portland cement. Roughly 6 million Mg year-1 are collected in baghouses at cement kilns, with most being recycled to the process or disposed of onsite. About 1 million Mg are shipped off-site as a by-product additive/stabilizer (for hazardous waste or biosolid stabilization) or as a lime substitute for use in agriculture. No specific data on the latter use appears to be available, nor any agronomic studies on use of the material. In 1992 USEPA ordered a study of kiln dusts prompted by the increasing use of by-product or waste fuels, including some hazardous petroleum and solvent by-products, as an accessory fuel in heating the kilns, which must reach very high temperatures in order to calcine the cement. In a report to Congress under RCRA, data indicated significant levels of dioxins, furans, metals (particularly Pb and Cd), and radionuclides in a range of kiln dust samples (USEPA, 1993a, 1993b). In 2002, regulation of this material was still under consideration by USEPA. Until further analytical data on contaminant levels and their fates in soils are available, caution is clearly indicated in use of kiln dusts as lime substitutes.

24.2.4 Biosolids and Municipal Solid Waste

No other by-product material has been as extensively studied for its agricultural value and environmental impact as has sewage sludge (biosolids), the solid residual material resulting from sewage digestion at municipal wastewater treatment facilities. Biosolids were used in Europe in the 1950s and 1960s on sewage farms to grow a variety of crops, and excessive uptake of heavy metals was eventually observed. Many studies conducted during the 1970s showed that high rates of sludge from industrial cities containing high metal levels resulted in enhanced plant uptake of Cd and other metals. Regulations followed that limited industrial metal inputs into water treatment plants, which considerably reduced metal levels in sludges (Chang et al., 1987). USEPA has encouraged land application of biosolids in order to recycle nutrients and avoid landfill costs, and has provided regulations to define high-quality biosolids for unrestricted use on crop land (Section 24.5.1). About 6.5 million Mg of biosolids (dry wt.) are generated annually in the United States, and currently 50% is land applied on agricultural, forestry, or reclaimed mined land; of the remainder, two-thirds is landfilled and the rest incinerated (NEBRA, 2007).

Trace elements in biosolids have been extensively documented in the United States and Europe, given the historical interest in land application of this material (Table 24.5). Mercury and Cd are the most toxic of the metals typically monitored in biosolids, and are elevated in some materials compared to background levels in soils (<0.05–1 mg kg $^{-1}$). Other metals listed in Table 24.5 can be hazardous when sludges of higher concentration are added at high rates to soils over a period of years. Potential hazards are discussed in Section 24.5.2. Regulatory limits have been established in the United States and the EU, as discussed in Section 24.5.1.

Organic contaminants in biosolids have not been regulated in the United States, on the rationale that insufficient data exists

on concentrations and that risk assessments have not been conducted for the wide range of potential compounds. The recent Targeted National Sewage Sludge Survey (USEPA, 2009) presents data for selected polyaromatic compounds, organobromine flame retardants, pharmaceuticals, steroids, and hormones; while concentrations vary over a wide range, mean levels are in the low ppm (mg kg⁻¹) range for most compounds, but reach 10–100 ppm for some common steroids and pharmaceuticals. Kester et al. (2005) report values for some volatile organics, polychlorinated biphenyl (PCB)'s, and dioxin-class compounds in biosolids, and suggest some new approaches to assessing risk of these compounds in biosolids-amended soils that may be implemented in the future.

The presence of potentially harmful microorganisms (bacteria, viruses, parasites) in sewage sludge was long thought to be the most significant public health risk associated with land application, particularly when biosolids were surface applied without incorporation. Airborne dispersal during application was thought to be the most common vector, since disease organisms were not expected to survive very long when mixed with

soil. Recent research confirms that pathogens from biosolids do not survive long in the soil (Rusin et al., 2003; Zaleski et al., 2005). Furthermore, the risk of bioaerosol infection during application may be significantly lower than previously thought (Brooks et al., 2005). USEPA defines Class A biosolids as having undergone advanced treatment (via heat, composting, or lime treatment) to eliminate pathogens, using fecal coliforms as the indicator organism. Class B biosolids have undergone treatment to reduce the number of human pathogens, but are likely to still contain them. According to the NRC (2002) about 60% of all biosolids generated in the United States are landapplied, with most of these being Class B solids. Pepper et al. (2008) have recently argued that risks to human health posed by human pathogens in land-applied Class B biosolids are low. In the United States, regulations regarding incorporation of land-applied biosolids vary from state to state. In Pennsylvania, for example, biosolids must be incorporated within 24h of application, while in Arkansas Class B biosolids must be incorporated within 6h of application, but Class A biosolids do not need to be incorporated. Regulations regarding incorporation are generally more strict in Europe than in the United States (NRC, 2002).

Biosolids are a good source of N and P for agronomic crops (Table 24.5), and many examples of their use on agronomic crops, forest trees, horticultural crops, and plants grown on reclaimed lands have been reported in the literature. Typically, application rates are based on either N or P content depending on relative concentrations and crop requirements. Some inorganic N is present, but because most must be mineralized by soil organisms, release occurs over several years. Potassium is low in most sewage sludges, and must be added as supplemental K fertilizer. Sludges have a variable effect on soil pH, depending on how they are processed (some are lime stabilized, and thus have considerable alkalinity); most sludges not containing free lime will acidify soil over time due to acid generated by nitrification, and pH must be monitored and adjusted.

Nearly 250 million Mg of municipal solid waste (MSW), including household garbage and some municipal and inert industrial wastes, are produced annually in the United States, and finding ways to reduce landfilling costs of this material is a growing industry (USEPA, 2007). Technological improvements in separation of plastic, glass, and metal from the MSW stream have suggested that the remaining 40%-60% of the waste, which is largely paper and food waste, might be composted and land applied. There are a number of firms with operational separation and composting units in the United States, subsidized by municipalities hoping to avoid capital expenses of building new Subtitle D (lined and monitored) landfills. Current production levels of compost (derived from MSW and/or manures) were estimated at 22 million Mg year-1 in 2007 (USEPA, 2007), but are likely to increase dramatically in the future (Stratton et al., 1995; Barker, 1997). Data are scarce, but the N and P contents of MSW composts are likely to be only 50% of the levels in biosolids, and mineralization rates are appreciably slower (Barker, 1997).

24.2.5 Composting and Mixing of By-Products

Composting refers to the process of stockpiling by-product materials under conditions that favor decomposition of organic materials to form a more stable product for use on soils. Carbon is lost as CO₂ during composting, resulting in a loss of bulk and concentration of nutrients compared to the original material (Barker, 1997). Nitrogen is also lost (as ammonia) during composting, but because more of the original C is lost than of the original N, composts generally have narrower C:N ratios than the corresponding original materials. The heat release accompanying composting kills many pathogens, and is an approved process for producing Class A biosolids for land application or for reducing pathogens in animal manures. Composting also eliminates odor from some materials, increases the density of the material (i.e., reduces bulk) and improves handling characteristics for land spreading. On the negative side, it may also narrow the N:P ratio of the finished product to such an extent that if the compost is used as the principal N source for a crop, over-fertilization with P could result. Composting is common for processing of MSW and biosolids prior to land application.

A wide range of literature is available on formulating and processing compost, as well as describing the microbiology involved; these specifics are beyond the scope of this review. It should be noted, however, that composting can nearly always benefit materials destined for land application, due to the changes noted above (a notable exception to this is the loss of N that occurs during composting). For some materials with active pathogens (particularly biosolids, MSW and food waste), wide C:N ratios, and/or objectionable odors, the advantages are significant, and if the material is to be used by home gardeners or near urban areas, proper composting is crucial to the successful marketing of the material (Stratton et al., 1995; Barker, 1997).

The concept of mixing by-product materials to obtain more optimum physical, chemical, or nutritional characteristics, in combination or apart from composting, has been used in formulating biosolid mixes with ash and cement kiln dust (Logan et al., 1997). Blending of organic (sludge) and inorganic (ash) materials has advantages in balancing nutrient content, adjusting pH, optimizing water content, and immobilizing contaminant metals. Currently, the additional costs of handling, blending, and storage of mixtures and composts are likely greater than the market value; costs of a manure/ pulp mill sludge composting operation were estimated at \$50-\$120 Mg⁻¹ (NCASI, 1984). Subsidies by contributing industries, as well as increases in demand and cost of landfilling, may make such operations feasible in the future. Hyatt (1995) has summarized information on potential marketing of composts in agriculture, and concludes that improving compost quality (particularly N content and availability) should increase farmer demand and establish pricing at a reasonable level for compost producers.

24.3 Soil Fertility Considerations in Land Application

The primary beneficial effect of land application of many by-products is the supply of essential plant nutrients to crops, particularly macronutrients (N, P, K). There are instances where the supply of other elements (Ca, S, or micronutrients) may be considered as the primary effect (such as in the case of gypsum), or the liming value may be appreciable. Additionally, some applications (particularly of organic materials) may increase SOM, improve soil structure, or increase water-holding capacity. Assessing the type and extent of beneficial effect to be achieved with a given type and rate of application is largely at the discretion of state officials in departments of agriculture or environmental regulation. It should be reiterated that a beneficial effect must be demonstrated or inferred for a given type of application, or such application may be construed as simply disposal.

24.3.1 Nutrient Content and Bioavailability

As mentioned in the previous section, most by-products contain significant quantities of several macro- and micronutrients, but it is the N content that is used most often as the basis for calculating application rates. This has historically been true because of the high N requirements of most crops coupled with the low N-supplying power of most soils. In order to understand the reasoning behind N-based application rates, it is necessary to know something about the chemistry of N in organic by-products.

Most organic by-products (i.e., manures and biosolids) contain two forms of N: organic and inorganic N. Organic N is chemically combined with C, H, and O while inorganic N occurs as nitrate (NO_3^-) and ammonium (NH_4^+). Both NO_3^- and NH₄⁺ can be taken up and used by plants, but organic N cannot. Ammonium and NO₃⁻ can be lost in large quantities from the soil, the former by denitrification (conversion to gaseous N₂O and N₂) and the latter by NH₃ volatilization. Denitrification is a microbially mediated process, which occurs under reducing (wet) conditions, while NH3 volatilization is an abiotic process, which occurs at high pH. The organic N fraction is not readily lost from the soil or by-product through these processes, but many microorganisms convert it into inorganic N through a process called mineralization. Finally, inorganic N can be converted into organic N by microorganisms that take up NH₄⁺ and NO₃⁻ ions and convert these into N-containing organic compounds. This process, called immobilization, temporarily reduces the amount of plant-available N (PAN) in the soil. The losses resulting from NH₃ volatilization and denitrification are permanent. A detailed discussion of the N cycle in soils and by-products is presented by Paul and Clark (1989), Sims and Wolf (1994), Brady and Weil (2008), and in Chapter 13.

Most of the N in organic by-products is in the organic form. The relative proportion of inorganic N in beef, swine, and poultry manure samples is approximately 8.1%, 5.8%, and 23%, respectively (Cabrera and Gordillo, 1995). When manures are mixed with water and stored as a liquid or slurry, mineralization occurs

to such an extent that in aged slurries and liquids there is more inorganic N than organic N (Cabrera and Gordillo, 1995). In virtually all manures the inorganic N pool is dominated by $\rm NH_4^+,$ although instances of high $\rm NO_3^-$ levels have also been reported.

Sims (1986) has proposed the following model for estimating PAN from soil applied manure:

$$PAN = A_i N_i + P_m N_o (24.1)$$

where

 $N_{\rm i}$ and $N_{\rm o}$ are the quantities of inorganic and organic N in the manure

 A_i is the fraction of inorganic N available for plant uptake P_m is the fraction of organic N that is mineralizable

The ability of this model to accurately predict the amount of PAN that will result from application of an organic by-product material to soil is dependent on the accuracy of the values assigned to the coefficients $A_{\rm i}$ and $P_{\rm m}$. The values assigned to $N_{\rm i}$ and $N_{\rm o}$ also have a major impact on the calculated PAN, but it is possible, at least in theory, to accurately measure these quantities. Much of the N in manures may be lost prior to land application during storage of the manure, which will decrease the values of both $N_{\rm i}$ and $N_{\rm o}$. The USDA Agricultural Waste Management Field Handbook (USDA, 1992) contains estimates of N, P, and K losses for several different types of animal manure stored under a variety of conditions. Organic by-products should be sampled and analyzed immediately prior to land application in order to account for storage losses not only of N, but of other nutrients as well.

There is a great deal of uncertainty involved in assigning values to the coefficients A_i and P_m . The coefficient A_i would have a value of 1 if there were no losses of inorganic N following application of the by-product, but this is seldom the case. Nitrogen losses can be significant depending on a host of environmental and management variables such as soil type and moisture, temperature, and method of by-product application (e.g., incorporated versus unincorporated). The combined losses of NO_3^- by leaching (Davis et al., 1995a) and denitrification (Johnson and Wolf, 1995) and losses of NH_4^+ by NH_3 volatilization (Thompson et al., 1990) and immobilization can cause significant losses (>50%) of the manure's inorganic N pool.

The proportion of the organic N (P_m) that is mineralizable will likewise depend on a variety of factors, including temperature and moisture conditions, the C:N ratio of the by-product, and the amount of N in the urea or uric acid forms, which are particularly susceptible to mineralization (Cabrera et al., 2005; Cusick et al., 2006; Diaz et al., 2008). In practice, P_m is not used per se in the calculation of application rates. Rather, the mineralization rate of organic N is represented by a decay series that gives the percentage of the organic N that is mineralized as a function of time after initial application of the by-product. The data in Table 24.6 are representative of typical decay series for organic N in several by-product materials. These data illustrate the following general concepts: (1) in fresh manures, a large

TABLE 24.6 Cumulative Mineralization of Organic N in a Variety of By-Products at Several Times after Initial Application

	Cumulative N Mineralized after		
	Year 1	Year 2	Year 3
Material		%	
Poultry manure (layer)	80	82	83
Swine manure (fresh)	75	79	81

percentage (>75%) of the organic N is mineralized during the first year after application; (2) rates of organic-N mineralization are generally higher for poultry manures than for swine or cattle manures; and (3) storage of manures causes decreased rates of mineralization following application because most of the easily mineralizable fractions of the organic-N pool have already been mineralized during storage. While data such as those in Table 24.6 can provide general guidance in nutrient management planning, in the United States, local Cooperative Extension Service or Natural Resource Conservation offices should be contacted for additional information that is tailored to specific, local conditions.

For biosolids, N mineralization rates vary considerably with treatment process; nitrogen in anaerobic sludges tends to mineralize more rapidly than in aerobic sludges (King, 1986; Table 24.6), but both release N less rapidly than manures. This is related to the partial decomposition that takes place during wastewater treatment, during which N is incorporated into more recalcitrant compounds. In general, composting of manures and other organic by-products leads to lower N mineralization rates and decreased N availability (Cabrera and Gordillo, 1995; Preusch et al., 2002; Gale et al., 2006; Munoz et al., 2008). Gilmour's mechanistic computer simulation model, which uses site-specific weather data and biosolids analytical data, has been used successfully to predict N mineralization from a variety of organic by-products under a variety of environmental conditions (Gilmour and Skinner, 1999; Gilmour, 2009).

In computing application rates based on N content, mineralization rates such as those in Table 24.6 should be used to predict N availability. Application rates should also account for any inorganic N present and N mineralized from previous years' applications to the same field. Losses of N from volatilization of stored manures can be appreciable, so reanalysis for N should be done if the material is stored for appreciable time periods.

By-products such as pulp and paper sludges, waste paper, and composts of various materials that contain low amounts of N (<1%) with C:N ratios of >50 probably have little potential to mineralize sufficient N for crop production. These materials will, in fact, immobilize N from the soil and may result in serious N deficiencies in crops planted soon after application. Additional (inorganic fertilizer) N should be applied to these soils to prevent N deficiency, or a period of several months should be allowed before planting to allow for decomposition to recycle N back into available forms.

By-product application rates are usually based on the N requirement of the crop that is being fertilized. However, many by-products are also good sources of other macro- and micronutrients, particularly P, Ca, Zn, and Cu. Perhaps because they contain so many different plant essential elements in available forms, manures have been found to be much more effective than synthetic fertilizers at restoring agronomic productivity to eroded and otherwise disturbed soils (Whitney et al., 1950; Aina and Egolum, 1980; Frye et al., 1985; Dormaar et al., 1988; Larney and Janzen, 1996). While some of the restorative ability of manures and other organic by-products may be due to improvements in the physical and biological properties of degraded soils, most researchers cite improved availability of N and P as the likely mechanism. Freeze et al. (1993) have pointed out that the restorative value of manures should make it economically feasible to transport manure farther than if it were to be applied strictly as an NPK source to nondegraded soils.

Gypsum is an example of a by-product used as a source of Ca, which can be a limiting nutrient on sandy and/or very acidic soils. Shainberg et al. (1989), Sumner (1993) and Ritchey et al. (1995) have reviewed the literature on the use of gypsum on acidic soils to increase available Ca in the subsoil in order to promote deeper rooting and water extraction by a range of crops. Yield increases are routinely obtained on a range of soils and crops with single applications of up to 10 Mg ha⁻¹, and the increases are maintained over >10 year. Such applications give a good economic return over time, and show no adverse environmental effects.

Wood ash has been used as a liming material (Lundström et al., 2003), a source of phosphorus and potassium (Erich, 1991), and as a micronutrient source (Nieminen et al., 2005).

24.4 Effects of Land Application on Soil Properties

Improvements in soil properties such as structure (aggregation), permeability, water-holding capacity, and CEC often do not have an immediate or consistent effect on crop yields, although soil scientists probably would agree that they are highly desirable. By-product additions, particularly of organic

materials, have the potential to improve many soil properties over a period of years, and these effects are consistent with the idea of beneficial reuse of these materials.

24.4.1 Physical Properties

Land application of by-products generally has been shown to improve soil physical properties (Wallingford et al., 1985), although there are several reports describing studies in which animal manures had either no effect or deleterious effects on some soil physical properties. Hileman (1967), for example, found no changes in either soil organic C content or bulk density as a result of 3 year of poultry litter applications to a silt loam soil at rates as high as 18 Mg ha⁻¹ annually. Similarly, Sharpley et al. (1992) found no consistent effect of long-term (up to 15 year) poultry or swine manure applications on soil physical properties. Weil and Kroontje (1979), on the other hand, reported that after 5 year of incorporating poultry litter at an annual rate of 110 Mg ha-1 the bulk density of the plow layer of a clay loam soil decreased from 1.1 to 0.8 g cm⁻¹. However, these authors also reported that a layer of partially decomposed manure had accumulated at the bottom of the plow layer, which greatly reduced the water percolation rate. Cattle manure has been shown to improve soil aggregation (Hafez, 1974; Adeli et al., 2007), to reduce soil bulk density (Tiarks et al., 1974), and to improve water-holding capacity of soils (Unger and Stewart, 1974).

A comprehensive study of the effects of long-term manure applications on soil physical properties was conducted by Schjønning et al. (1994) in Denmark. Farm yard manure (FYM) or inorganic fertilizer was applied for 90 year to plots on a sandy loam soil. The FYM treatments had significantly higher organic C contents, lower bulk densities and decreased compactibilities compared to the inorganic fertilizer treatments. The results of this study provide particularly compelling evidence for the beneficial effects that long-term manure applications have on soil physical properties. It is expected that other types of organic byproducts might have similar effects.

In a review of literature on effects of biosolid application on physical properties, increases in soil organic C of 0.5%–2.5% were noted over 2–5 year at higher rates (20–100 Mg ha⁻¹) of sludge additions (Hill and James, 1995). Increases in C are typically correlated with lower bulk density, greater aggregation and aggregate stability, and improved water retention. Preliminary results on a sandy soil in Georgia showed improved aggregate stability and water-holding capacity with primary and secondary pulp mill sludge added at rate of 40 Mg ha⁻¹ (Cochran et al., 1997).

Infiltration and hydraulic conductivity of sludge-amended soils is highly variable. The time and rate of application can have large effects. Freshly applied sludges may lower saturated hydraulic conductivity at the surface due to pore clogging, but incorporated sludge additions over time tend to improve infiltration due to better aggregation and macroporosity, leading to less surface crusting under rainfall (Hill and James, 1995). Price and Voroney (2007) found high rates (100 Mg ha⁻¹) of a paper mill biosolid increased infiltration rate and aggregate size and

decreased bulk density on four different soils over 3 year in a field experiment in Canada.

Shiralipour et al. (1992) reviewed the literature on the impacts of MSW compost on soil physical properties. Typically, high (>100 Mg ha⁻¹) rates of application have been added to degraded or very sandy soils. In most cases, SOM levels and water retention increased and bulk density decreased with compost additions.

Several studies have suggested that fly ash applications may be used to increase water-holding capacities of very sandy soils at high rates of application (100–300 Mg ha⁻¹) due to addition of fine particles (Ghodrati et al., 1995). Gypsum is widely used in semi arid regions on sodic soils to improve aggregation and permeability, and by-product gypsum should perform equally well as the mined type mostly in use (Shainberg et al., 1989). Surface-applied gypsum also improves infiltration rates of weathered acidic soils over several rainfall events due to its flocculating effect on soil clays (Miller, 1987). Radcliffe et al. (1986) demonstrated that given sufficient time to move into the subsoil, surface applications of gypsum reduced the penetration resistance of subsoil hardpan layers.

24.4.2 Biological Properties

There do not appear to be a large number of published reports on the effects of manure applications on soil biological properties. Because of the great diversity of soil microorganisms and the complexity of the interactions within the soil microbial community, studies tend to focus on how manure applications affect either a single group of soil organisms or the soil microbial biomass as a whole. For example, Christie and Beattie (1989) found that soil microbial biomass C and N decreased with increasing rates of applied swine manure slurry, but increased with increasing rates of applied cattle manure slurry. Adeli et al. (2007) reported that 3 year of broiler litter application at a rate of 6.7 Mg ha⁻¹ increased soil microbial biomass C 28% relative to the unlittered control. Eight years of pig slurry or solid cattle manure applications were reported to increase numbers of bacteria, actinomycetes and fungi in soils (N'Dayegamiye and Côté, 1989), while 19 year of pig and cattle slurry additions to grassland significantly decreased vesicular arbuscular (VA) mycorrhiza infection of plant roots (Christie and Kilpatrick, 1992). The reduction in VA mycorrhiza infection apparently caused by application of manure may not be a serious cause for concern, as the impact of mycorrhizal infection on plant nutrition is greatest in low fertility soils, and declining mycorrhizal populations in nutrient-rich, manured soils may have little or no impact on plant growth. Mårtensson and Witter (1990) concluded that the changes that they observed in populations of N-fixing soil organisms brought about by applications of manure were, in fact, caused by manure-induced changes in soil pH.

A potential concern in by-product application is the possibility of chronic toxicity to soil microbial populations caused by low levels of added contaminants. Such concerns have been voiced particularly in the European scientific community. Although no systematic body of information is currently available to evaluate

this possibility, data from Europe suggests there are levels of some trace metals that do inhibit overall microbial activity and specific groups of organisms (Smith, 1996). Typically, these levels are greater than regulatory limits on metal loadings of soils (Section 24.5.1), but in certain cases (e.g., Zn; see Smith, 1996), lower metal levels may inhibit some soil microbes. Cela and Sumner (2002) showed that nitrification in three soils was inhibited in the laboratory by Cu and Ni added as inorganic salts at rates of about 100 ppm, but solubility of metals was very high in these experiments. Current risk assessment models are not specifically designed to consider these kinds of effects.

A recurring question is the safety of land-applied biosolids and manures in terms of disease vectors. Treatment methods to eliminate pathogenic organisms from biosolids to create Class A (pathogen-free) biosolids are used on about one-half of the landapplied biosolids in the United States, and are mandatory in Britain and other EU countries. The available data support the contention that these are effective treatments when executed properly, although the study of microbial and virus agents in biosolids is perhaps the most difficult aspect of assessing risk to the public, due to the difficulty of quantifying these organisms (Angle, 1994). Recent applications of risk assessment to pathogens in land-applied wastes has been reviewed by Gerba and Smith (2005), along with documentation of types of disease organisms present and past disease outbreaks associated with manure applications. Anecdotal evidence of human illness related to Class B biosolids applications have been reported in the literature (Harrison and Oakes, 2002; Khuder et al., 2007), and the National Research Council's (2002) report on biosolids emphasized the need for better information on pathogen survival, dispersal, and relationship to human disease, as well as improved enforcement and monitoring of current regulations. As mentioned previously in Section 24.2.4, recent research indicates that the public health risks associated with land application of pathogen-containing biosolids may be lower than originally thought (Zaleski et al., 2005; Brooks et al., 2005; Pepper et al., 2008).

According to Guan and Holley (2003), the major pathogens present in swine manure (*Escherichia coli* O157:H7, *Salmonella*, *Campylobacter*, *Yersinia*, *Cryptosporidium*, and *Giardia*) can be eliminated by holding the manure at 25°C for 90 days. Holley et al. (2006) reported that under optimal conditions *Salmonella* can survive for up to 180 days in soil following application of swine manure. Soupir et al. (2006) reported finding large numbers of *E. coli* in runoff from fields fertilized with "cowpies," liquid dairy manure, or turkey litter. *Campylobacter* spp. and *E. coli* have also been found in runoff from poultry litter amended fields (Duggan et al., 2001).

24.4.3 Chemical Properties

The impact of by-product amendments on soil chemical properties depends strongly on the types and rates of by-products applied. Materials might be separated into those that are largely organic, those that are inorganic and alkaline, and gypsiferous by-products.

Organic materials (manures, biosolids, pulp mill sludge, MSW compost) typically increase soil organic C, and therefore increase CEC due to the high negative charge on organic matter. The amount of charge varies with the level of C increase, as well as the pH, since the CEC is of the variable charge type. Increases in CEC have been measured in amended soils in proportion to the C increases, but have also been noted to decline as decomposition processes reduce the organic C levels in years following a single application (Hill and James, 1995). The capacity of soils to specifically (strongly) adsorb metal cations is similarly a function of organic matter, and partially explains the lower plant availability of metals added in biosolids compared to inorganic salts (Smith, 1996).

Organic by-products also cause short-term shifts in soil pH and Eh (redox potential) due to the highly reducing nature of many organic by-products and microbial activity (and hence O₂) depletion) resulting from their addition. Anaerobically digested biosolids and uncomposted animal manures added at high rates (>20 Mg ha⁻¹) may result in temporary pH increases of 1–2 units, and decreases in Eh to 0 V or below within a week of application. In a study of swine manure added at 100 Mg ha-1, considerable solubilization of Fe and Mn oxides was observed during this period, although trace metal solubility did not increase appreciably due to adsorption onto organic matter (Miller et al., 1985). Within 2-3 weeks, Eh and pH returned to near initial levels. Although biosolids may be applied at high rate (>20 Mg ha⁻¹) to supply adequate N for crops, animal manures are usually applied in the 4-10 Mg ha⁻¹ range. These lower rates will help prevent the effects discussed above.

Inorganic alkaline by-products such as fly and wood ash, kiln dusts, and lime obviously impact soil pH, and rates should be adjusted based on the CCE of the material to reach a desired pH level. Some of these materials (such as alkaline fly ashes) also contain considerable soluble salts, which initially increase electrical conductivity (EC) of soil pore water when land applied that can injure salt-sensitive plants or seedlings. These salts are rapidly leached out of the root zone within a few rainfall events, and typically have no residual effect on plant growth.

Gypsum is soluble in water (2.5 g L^{-1}) and this solubility has been used to great advantage on soils with acidic subsoils to encourage deeper rooting of a range of crop plants (Shainberg et al., 1989). High application rates (10-20 Mg ha⁻¹) of byproduct gypsum result in appreciable increases in exchangeable Ca, with a decrease in exchangeable Al in subsoil horizons of Ultisols and Oxisols over a several-year period. Overall, CEC also increased possibly by the ligand exchange of SO₄²⁻ for OH- (Souza and Ritchey, 1986); pH in the subsoil is not appreciably changed. The increase in base saturation and Ca availability increased root distribution down to 1 m, resulting in greater water extraction and yield improvements for alfalfa of up to 100% compared to unamended control plots (Shainberg et al., 1989; Sumner, 1993). Both PG and FDG are similarly soluble, and have identical effects on subsoil chemistry and crop yields.

24.5 Environmental Aspects of By-Product Applications

The benefits of recycling nutrients and organic material to crop production via land application must be balanced against the potential for environmental degradation and threats to human health of such applications. The risks of such effects can be serious, even for seemingly innocuous materials such as animal manures that have been used in agriculture for centuries. Despite volumes of research findings compiled over the past 50 years, the assessment of these risks is a major topic of research today.

The degree of both scientific debate and public contention over the public health effects of land application practices has increased significantly over the past decade. Some of this controversy is due to reevaluation of the risk of well-studied factors (trace metals, nutrient export, pathogens), as well as to the consideration of relatively "new" risk factors in land-applied materials (hormones, pharmaceuticals, trace organics). Debates within the scientific community (McBride, 2003) and critical reviews of policies by independent agencies (National Research Council, 2002) have fueled public skepticism of land application regulations, which some perceive as industrial/governmental attempts to "dump toxic waste" on rural farmland.

Response to such criticism in the United States has been continual reevaluation of risk assessment models designed to quantify human health response to loadings of contaminants resulting from land application (Kester et al., 2005). These models used "risk pathways" (e.g., transfer from soil \rightarrow plant \rightarrow human) to quantify contaminant transfer from amended soil to humans, using the idea of a "most exposed individual" as one who (for example) obtains most (or all) of their food from waste-amended soil. Maximum allowable contaminant loading limits are set based on an acceptable increase in human health impacts (e.g., increase in cancer occurrence of 1 per 10^5 or 10^6). Such an analysis requires large amounts of basic data on contaminant behavior and toxicological response, and involves assumptions and judgment decisions that introduce varying degrees of uncertainty into the final result.

European countries have set (in many cases) more stringent rules for soil contaminant loadings than has EPA in the United States, based on other considerations including relation of contaminant increases to native or background levels in soils (Smith, 1996). This may in part be due to application of the "precautionary principle," as discussed previously (Section 24.1.3).

In the United States, state environmental agencies are largely responsible for implementation of federal regulations regarding land application. Where no such regulations exist, state agencies develop their own guidelines or consider materials on a case by case basis. State departments of agriculture are involved in registering by-products as fertilizers or lime substitutes, and may not effectively interact with state environmental agencies to ensure safe use of these materials. There are examples of quite hazardous materials being land applied where state agencies have failed to coordinate (Wilson, 1997).

24.5.1 Governmental Regulations Concerning Land Application

The USEPA regulates the handling, disposal, and land application of wastes under Congressional authority, and through rule making associated with legislative acts. Nearly all such regulation deals with industrial and municipal by-products, with agricultural by-products being expressly exempt (this exemption may change as manure applications are linked with water quality degradation). State departments of agriculture and/or environmental affairs implement federal regulations, and may modify them in some cases. The EU has also adopted resolutions, implemented by member countries, regulating handling and use of wastes.

The primary legislation affecting industrial wastes in the United States is the RCRA of 1976, which defines waste and, in particular, the concept of hazardous waste, which must be specially handled and typically cannot be land applied (40 CFR 264-5). Hazardous waste is liquid or solid material derived from a manufacturing process that has one of the following characteristics: (1) corrosivity, typically due to pH > 12 or pH < 2 of liquid or liquid derived from a solid; (2) ignitability or explosivity largely associated with organic solvents and petroleum wastes; or (3) toxicity, as determined by trace contaminant levels of leachates as measured in an acetate buffer at pH 5.2 (Toxicity Characteristic Leaching Procedure, TCLP). The presence of certain toxic organics and radionuclides automatically classifies a waste as hazardous. Hazardous wastes fall under Subtitle C of RCRA, and must be transported and disposed of in a proscribed manner (e.g., hazardous waste landfills); nonhazardous waste falls under Subtitle D, and can be disposed of in less secure (but still lined and monitored) landfills, and may be potentially land applied.

MSWs, FGD, most kiln dusts (not containing restricted trace contaminants), most pulp and paper by-products (except highly alkaline residues or high dioxin sludges), and many other more or less inert by-products are classified nonhazardous. Biosolids are exempt, being covered under special rules of 40 CFR 503. Fly ash is also exempt, but may be restricted in use if it fails the TCLP. Flue dusts typically fail the TCLP, but may be used as micronutrient fertilizers if Pb and Cd are low. PG has been regulated by USEPA due to its radionuclide content. Animal manures and most agricultural by-products are currently exempt and unrestricted.

Biosolid use on land is regulated separately under authority of the CWA in 40 CFR 503 (USEPA, 1993a, 1993b). This ruling specifies treatment for pathogen reduction as well as sets upper limits for metal concentrations, as well as application methods for pathogen vector control and use of materials at agronomically appropriate rates (i.e., based on nutrient contents). "Exceptional quality" (Class A) biosolids are defined as having been treated (via heat, lime stabilization, etc.) to stabilize organic matter and reduce total pathogen load, and also must have metal concentrations below certain limits (Table 24.7); these materials can be used without restriction or record-keeping. Use of materials that do not meet "exceptional" criteria (referred to as Class B) is more

		USEPA			EU

TABLE 24.7 USEPA and EU Limits for Metals in Biosolids and Loading Rates for Land Application of Biosolids (Annual and Lifetime)

Sources: USEPA. 1993a. Cement kiln dust-Report to Congress. Available at http://www.epa.gov/osw/nonhaz/industrial/special/ckd/cement2.htm (accessed May 2009); Smith, S.R. 1996. Agricultural recycling of sewage sludge and the environment. CAB International, Wallingford, U.K.

- ^a Lower value is for high quality unrestricted use; higher value is ceiling for application.
- ^b Limits for these metals are tentative.
- ^c Limits on Mo are being removed by USEPA.
- d Lower value for soils at pH < 6, higher value for pH > 7.
- ^e Values in parenthesis are U.K. limits; no EU values specified for these metals.
- ^f USEPA is considering reducing Cd loading to 21 kg ha⁻¹ at USDA's request.

restricted in terms of application conditions in order to limit pathogen vectors, and metal additions must be recorded to limit annual and lifetime loading rates (kg metals ha⁻¹) for a given site.

Current USEPA regulations allow metal additions that are considerably higher than previous regulations, and are, in general, greater by a factor of 5-15 for most metals than EU soilloading rates (EU Directive 86/278/EEC; Smith, 1996; Table 24.7). Allowable metal concentrations do not differ significantly between the two, but maximum rates of application in Mg ha-1 allowed (computed as [loading in kg ha-1]/[concentration in mg kg $^{-1}$] \times 1000) are quite different. Using the lower metal concentration limits for EU sludges and corresponding annual metal loading rates, only about 5-10 Mg ha⁻¹ year⁻¹ of sludge can be applied, compared to 50 Mg ha⁻¹ year⁻¹ for the USEPA limits. Depending on N and P needs of the crop on a given site and the available nutrients in the biosolids, more than 10 Mg ha⁻¹ may be needed to meet annual nutrient needs, therefore requiring supplemental inorganic fertilizer (Section 24.3.1). Rates based on N or P required would seldom exceed the 50 Mg ha-1 limit for metals based on USEPA values.

Metal limits in 40 CFR 503 are often applied to the utilization of other by-products for land application. This is probably justified for other organic by-products such as MSW compost or pulp and paper sludges, which have a similar matrix and impact on soil chemistry. However, for inorganic materials such as gypsum, fly ash, and by-product dusts with a largely inorganic matrix, this could lead to increases in leachable or plant-available metals above safe levels, due to the fact that metals in an organic matrix are generally less soluble (Section 24.5.2).

24.5.2 Soil and Food-Chain Contamination

Contamination of soil and subsequent uptake by plants and transfer to animals are major risk pathways for metals and organic contaminants in by-products applied to land. A large body of information is available concerning such risks for biosolid applications, summarized recently in a number of books and review articles (Chang et al., 1987; Chaney, 1994; Hue, 1995; Smith, 1996). For other types of by-products, there is no systematic evaluation of contaminant effects, but there are data that allow some interpretation of potential risks, particularly using the experience with biosolids as a guiding example.

24.5.2.1 Trace Inorganic Contaminants

Trace metals and metalloids have a long history of research and regulation in land application. Risk assessment analysis of trace inorganics with respect to leaching, food chain impact, and direct soil ingestion form the basis of USEPA biosolids regulation. These elements are typically insoluble in soils and generally considered to have limited plant availability and leaching potential due to their strong affinity to organic materials when applied in manures and biosolids. Basta et al. (2005) note that this strong adsorption, coupled with inherent limits to plant uptake, allow relatively high loadings of trace elements to soils without environmental consequences. However, there are many "exceptions" for specific element/plant/soil combinations that may short-circuit these processes (McBride, 2003).

Zinc, copper, and nickel tend to be toxic to plants before they accumulate sufficient tissue concentrations to affect animals or humans. As a result, over application tends to kill or stunt plants, preventing poisoning of animals or humans consuming them. Zinc is readily translocated to plant shoots, while Cu and Ni are toxic to plant roots without much movement to leaves. None of the elements moves appreciably into plant seeds. All are more soluble at pH < 6, and therefore, careful monitoring of pH can limit plant availability on amended soils. The 40 CFR 503 limits for these metals are quite high, and many by-products contain appreciable concentrations. In organic materials, solubility is limited by complexation by organic matter; in inorganic materials such as flue dusts or fly ash, solubilities may be significantly higher (Ainsworth and Rai, 1987; Hue, 1995). Solubility decreases with time after application due to reactions with soil mineral surfaces.

Because swine and poultry manures may contain elevated Cu and Zn due to feed supplementation, repeated applications can result in elevated levels of total and extractable Cu (Anderson et al., 1991; del Castilho et al., 1993; Kingery et al., 1994) and Zn (Christie and Beattie, 1989; Kingery et al., 1994) in soils, but it is still not clear whether this is a significant problem in terms of plant uptake and subsequent transfer through the food chain.

Similarly, lead, chromium, and mercury are not taken up by plants to any degree, and thus are not limited by risk pathways that involve plants. These elements are strongly adsorbed by soil and are quite insoluble. Rather, direct soil ingestion by children living on amended soils is the limiting pathway for these metals. This scenario assumes 1–6 year old children ingest 200 mg day⁻¹ of contaminated soil, increasing risks of Pb-related neurological damage (Smith, 1996). Similarly, animals in grazing pastures may ingest considerable amounts of by-product directly as soil and material coating leaves, and thus are exposed to these metals even without direct plant uptake. For these metals, 40 CFR 503 limits should be fairly readily transferred to other by-products, given that no soil or plant chemistry is involved in the risk assessment.

Cadmium is perhaps the most important potential contaminant of food supplies on amended lands. Being relatively soluble in soils (particularly at low soil pH) and chemically similar to Zn, it is readily taken up by crop plants and is quite toxic to humans. Cereal grains in the EU must contain less than 0.1 mg kg⁻¹ Cd to be marketed (Smith, 1996). The 40 CFR 503 limit of 39 mg kg⁻¹ Cd in biosolids has been criticized as overly liberal, and is based on a risk pathway involving direct ingestion of sludge or soilsludge mixtures by children, rather than plant uptake. Chaney (1994) cites studies that indicate that Cd uptake by plants on biosolids-amended soil is seldom excessive due to the high Zn levels usually present, but also notes that some grains in the United States exceed the EU Cd limit, and that lower Cd loadings might be desirable. He indicates that 21 mg kg⁻¹ Cd in biosolids (and a 21 kg ha⁻¹ loading limit) may be necessary to limit plant uptake to acceptable levels.

Arsenic, selenium, and molybdenum typically are present in lower concentrations in biosolids, but may be elevated in wood and fly ash and in various by-product dusts. Fly ash from high S coals in particular has elevated As contents, as well as

appreciable Se and Mo (Table 24.3). These elements are anionic in soils, which means they are more soluble at higher pH (opposite of the metallic trace elements) due to strong adsorption on Fe oxides at low pH. Both Se and Mo are required trace elements for animals, and Se has been cited as deficient in human diets in the eastern United States (Adriano, 1986). Both are toxic at higher concentrations. Levels of As or Se in food or feed crops above 0.25-1 mg kg⁻¹ are considered a potential hazard. Arsenic is similar in chemistry to P and is therefore taken up by plants, although a wide range of factors influence uptake. While poultry litter contains 15-30 mg kg⁻¹ As due to additions to feed (Toor et al., 2007), Staed et al. (2009) found no accumulation of As in the top 8 cm of soil after repeated applications of poultry litter. Molybdenum is a concern for grazing ruminants, which suffer Mo-induced Cu deficiency if the Cu/Mo ratio of forage falls below a value in the range of 2 (Miltimore and Mason, 1971; Chang et al., 1987) to 5 (Suttle, 1991). It is taken up in large amounts by legumes at soil pH > 6.5, however, and O'Connor et al. (2001) have suggested a limit of 40 kg ha⁻¹ be established as the maximum Mo loading on biosolids-amended soils using a risk assessment based on livestock grazing.

24.5.2.2 Trace Organic Contaminants

These are present in many types of by-products, and may classify an individual material as hazardous under RCRA if present in sufficient quantities. Safe levels in by-products for land application have not been determined, although future revisions of the 40 CFR 503 rule for biosolids may address limits for specific compounds. Rule making on these contaminants has been limited by difficulty and cost of analysis, and limited studies in the literature on occurrence, reactions, and transformations in the environment (Hue, 1995).

Smith (1996) has summarized types of toxic organics likely to be found in biosolids. The most important classes, each of which contains an array of individual compounds, are polychlorinated dibenzo-*p*-dioxins and furans (PCDD/Fs), polynuclear aromatic hydrocarbons (PAHs), and PCBs. All are moderately high molecular weight, nonvolatile and insoluble compounds that adsorb strongly to soil, show little tendency to be taken up by plants, and degrade slowly in the soil environment. Biosolids typically contain <1 mg kg⁻¹ of PCBs and PAHs, and considerably less PCDD/Fs.

Pulp and paper mill sludges, as well as wood and fly ash have been suspected of containing dioxins and furans (PCDD/Fs) originating from Cl₂ treatment during pulp bleaching and from combustion, particularly in the presence of Cl salts. A 1988 survey of 104 kraft mill sludges derived from Cl₂ bleaching processes gave TCDD (dioxin) values averaging 70 ng kg⁻¹ and 600 ng kg⁻¹ TCDF (furans) (Camberato et al., 1997; Miner, 1997). Provisional standards for materials to be land applied have been set at 10–20 ng kg⁻¹ based on toxic equivalent (TEQ) of 2,3,7,8-TCCD, the most toxic of the dioxin compounds. Non-Cl₂ bleaching methods are being widely adopted by the paper industry, and result in TEQs uniformly <10 ng kg⁻¹. Interestingly, six

processed municipal biosolids contained from 13 to 75 ng kg⁻¹ TEQs, significantly higher than the clean technology pulp sludges (Miner, 1997).

Fly ash from boilers burning wood and fossil fuels at pulp mills may contain significant dioxins depending on boiler configuration and fuel type (Someshwar, 1996). Computed TCDD TEQs mean values ranged from 20 to 400 ng kg⁻¹, with one data set averaging 1800 ng kg⁻¹ when salt-saturated wood was used as fuel.

Overall, considerably more study on organic contaminants is required, and USEPA is likely to consider organics in revisions of the 40 CFR 503 rule, despite difficulties in obtaining data and assessing risks for these compounds (Smith, 1996).

24.5.2.3 Antibiotics, Hormones, and Pesticides

Some land-applied by-products, notably animal manures and biosolids, contain variable levels of antibiotics, hormones, and pesticides. They are discussed separately here because an extensive amount of recent research has revealed that these compounds, particularly antibiotics and hormones, may pose unique, largely unanticipated and very serious threats to the environment, including potential threats to human health.

Antibiotics are used in livestock and poultry production in two ways. In therapeutic use, antibiotics are administered at relatively high dosages to animals that are exhibiting symptoms of a particular disease. Subtherapeutic use, on the other hand, involves adding antibiotics at lower rates to the animals' feed, regardless of whether they are exhibiting symptoms, to promote weight gain and growth rate in the animals. In their early review of this subject, Sims and Wolf (1994) list 13 different antibiotics (along with 5 coccidiostats and 7 larvacides) that have been added to poultry diets. It is estimated that 75% of these antibiotics are not absorbed by the animals and are excreted in the feces and/or urine (Chee-Sanford et al., 2009). When these wastes are land applied, the antibiotics they contain may enter the soil, move through the vadose zone to groundwater, or enter surface waters through runoff and erosion (Halling-Sørensen et al., 1998). Among the many factors that control their ultimate fate in the environment are water solubility, tendency to adsorb to soil colloids, and resistance to both biotic and abiotic degradation (Gavalchin and Katz, 1994; Campagnolo et al., 2002; Burkhardt et al., 2005; Hamscher et al., 2005; Kester et al., 2005; Sarmah et al., 2006a, 2006b; Dolliver and Gupta, 2008a, 2008b; Sanders et al., 2008; Chee-Sanford et al., 2009). Antibiotic uptake by plants from soil fertilized with animal manure has also been reported (Tietjen, 1975; Kumar et al., 2005; Dolliver et al., 2007).

Bacteria inhabiting soil repeatedly treated with animal manures containing antibiotics (e.g., tetracycline) develop resistance to these antibiotics (Khachatourians, 1998; Sengelov et al., 2003; Heuer and Smalla, 2006). This is of particular concern when the resistant organisms are also human pathogens (e.g., salmonella, streptococcus, etc.). According to Gilchrist et al. (2007), the reduced effectiveness of several classes of antibiotics for treating infections in humans may be a result of the increasing land application of animal manures containing antibiotics. Along with the World Health Organization, Gilchrist et al.

(2007) has called for a gradual phasing-out of the subtherapeutic use of antibiotics in animal agriculture. Until that is achieved, others have suggested that all manure that is to be land applied should be composted first. Composting and in some cases just stockpiling reduces the number of antibiotic resistant bacteria in manure (Dolliver et al., 2008; Sharma et al., 2009).

Much less information is available in the literature regarding the presence of antibiotics in biosolids. This is presumably due to the fact that the quantity of antibiotics used therapeutically to treat human infectious diseases is small compared to the quantity used in animal agriculture. As a result, biosolids contain much lower levels of antibiotics than do animal manures. However, biosolids do contain what are referred to as pharmaceuticals and personal care products (PPCPs). Xia et al. (2005) list the most common PPCPs found in the effluent of wastewater treatment plants. Information on the relationship between concentrations of PPCPs in soil and land application of biosolids containing PPCPs is scarce, as is information on the fate and transport of PPCPs in biosolids-treated soils. Additional research is needed in this area.

Biosolids and animal manures contain natural steroidal hormones (e.g., 17β-estradiol, testosterone) and synthetic compounds with estrogen-like activity (e.g., 17α-ethynylestradiol, 4-nonylphenol) (Bolan, 2004; Lorenzen et al., 2006; Sarmah et al., 2006a, 2006b). Such chemical compounds are collectively referred to as endocrine disrupting chemicals (EDCs) because of their effects on endocrine system function in both humans and other animals (Colburn et al., 1993; Sonnenschein and Soto, 1998). Land application of biosolids and manures may be an avenue by which these EDCs are introduced into the environment. Shore et al. (1995) and Nichols et al. (1997) were among the first to report runoff losses of 17β -estradiol from fields fertilized with poultry litter. Several recent studies indicate that decomposition of the EDCs present in manures and biosolids is relatively rapid under conditions representative of a well-aerated, temperate region soil (Colucci et al., 2001; Jacobsen et al., 2005; Lorenzen et al., 2006). On the other hand, Sangsupan et al. (2006) and Lægdsmand et al. (2009) reported significant leaching of EDCs through intact soil columns, suggesting that EDC contamination of groundwater could occur under conditions of preferential flow. What effects, if any, these land applied EDCs have on aquatic organisms and humans is unknown at this time.

The most common class of pesticides found in beef cattle manures are parasiticides such as organophosphates, carbamates, and synthetic pyrethroids (Khan et al., 2008). Sims and Wolf (1994) report that a variety of coccidiostats and larvacides are added to poultry diets. Very little is known about the environmental fate and transport of these substances once they are introduced into the environment through the land application of animal manures. Additional research is urgently needed.

24.5.2.4 Nitrate and Ammonium

These are included here as they can cause toxicities to plant and animals on by-product-amended soils. Manures (especially poultry) or biosolids may contain appreciable inorganic NH₄, or rapidly mineralize N as $\mathrm{NH_4}$ under optimal conditions. This $\mathrm{NH_4}$ can be converted to $\mathrm{NH_3}$ gas at high pH > 7. Ammonia is quite toxic to plants, and may cause appreciable damage to crops, especially seedlings (USDA, 1992). In addition, high levels of $\mathrm{NH_3}$ can cause $\mathrm{NO_2}^-$, which is very toxic to plants, to accumulate in soil (Schumann and Sumner, 1998).

Nitrate may accumulate in plant tissues during certain times of the year in response to high N levels in sludge- or manureamended soils. Forage crops on soils heavily amended with biosolids have been found to contain high levels of nitrate (400 mg kg $^{-1}$ N as NO $_3$), particularly when the forage is drought stressed. Ruminants are quite susceptible to NO $_3$ poisoning, and significant mortality of cows fed with hay at such NO $_3$ levels has been observed. The level at which NO $_3$ is toxic depends on the animals' condition and whether they have been acclimated to nitrates in the diet.

24.5.3 Water Quality Considerations

The adverse impacts of improper land application of by-products on both surface and groundwater quality can be severe. However, by far the greatest incidence of such impacts involves N and P in animal manures, rather than trace contaminants in industrial by-product, and such problems are commonly traced to poor management or over-application of manures. On the other hand, many instances of water contamination can be traced to disposal of wastes in landfills or stockpiling of by-products at the point of production. The reasonable reuse of these materials on crop land, where appropriate, would therefore reduce the likelihood of water contamination.

Applications of animal manure can cause leaching of high levels of NO_3^- to groundwater and enrichment of surface waters with P contained in runoff. Instances of groundwater pollution with NO_3^- in England are now so common that legislation is being considered to limit N applications to crop land to <200 kg ha⁻¹ (Smith, 1996). Both the United States and United Kingdom limits are $10 \text{ mg } NO_3^- N L^{-1}$ in groundwater, and soils receiving high rates of manures or high N sludges often release NO_3^- rapidly enough to pollute shallow aquifers, especially on sandy soils (Bergström and Kirchmann, 2006).

In recent years, as point sources of water pollution have been identified and eliminated, the importance of nonpoint source water pollution has become more apparent. Agricultural activities are believed to cause a considerable amount of the nonpoint source pollution of both surface and groundwater in the United States and other developed countries. Furthermore, land application of animal manures is now suspected of being a major P source, which is frequently the nutrient limiting biological productivity in freshwater lakes (Sharpley and Rekolainen, 1997). The recent outbreak of *Pfiesteria*-like organisms in Chesapeake Bay, whose toxins are believed to have caused memory loss in humans and the death of thousands of fish (Martin and Cooke, 1994), may be linked to elevated P levels in the Bay, which is surrounded by an area of intensive animal production (MacIlwain, 1997).

The nutrient that is of primary concern with regard to water pollution resulting from land application of animal manures is P (Daniel et al., 1994; Sharpley et al., 1994). The relative amounts of N and P contained in many animal manures are such that when application rates of manure are calculated based on the N requirement of the crop, the amount of P added often exceeds the P requirement of the crop. This results in accumulation of P in the soil (Sharpley et al., 1993; Slaton et al., 2004). While most soils have the capacity to fix, or immobilize, large amounts of P, this capacity is finite and can be exceeded if N-based manure applications are made repeatedly over a period of years. As the soil's ability to fix P declines, a greater proportion of the P in the soil exists in a water-soluble form (as the orthophosphate anion), which is highly susceptible to edge of field loss in runoff. Except in very sandy soils, which have low P-fixation capacities, leaching of P to groundwater is generally not considered to be a major loss mechanism of P from manure-amended soils. Runoff of soluble P from surface-applied manure can be a significant contributor to soluble P in surface waters.

Loss of N from fields receiving animal manures is also a concern. While most of the N in animal manures is in the form of organic N compounds or $\mathrm{NH_4}^+$, mineralization and nitrification can result in the formation of large amounts of $\mathrm{NO_3}^-$ following manure application if the soil is warm and well-aerated (Johnson and Wolf, 1995). Unlike the $\mathrm{H_2PO_4}^-$ anion, $\mathrm{NO_3}^-$ is not fixed in appreciable quantities by most soils and is, therefore, more likely to be leached through the soil to groundwater (Unwin, 1986; Adams et al., 1994; Bergström and Kirchmann, 2006).

In addition to N and P, it has been shown that runoff from manure-amended soils can also contain pesticides and hormones. Pote et al. (1994) found concentrations of cyromazine, a feed-through larvacide, as high as $101 \, \mathrm{g \ L^{-1}}$ in runoff from plots that had been treated with $17.7 \, \mathrm{Mg \ ha^{-1}}$ of caged layer manure. Cyromazine was not detected in water samples collected from lysimeters placed at a depth of $60 \, \mathrm{cm}$ in the soil for up to 1 year after the manure was applied.

Nichols et al. (1997) found elevated levels of the hormone 17β -estradiol in runoff from poultry litter-amended pastures. The effects that compounds such as these may have on aquatic ecosystems are not currently known.

The potential for pollution of surface waters resulting from land application of animal manures can be minimized if certain management practices are followed (Daniel et al., 1994). The primary factors affecting quality of runoff from animal manureamended fields are application rate, method of application, and timing of application (Sharpley, 1997). In the case of P, to this list should be added the soil P status (or the degree to which the P-fixation capacity is already saturated) because it is well documented that the amount of P in the surface soil directly influences the amount of P in runoff (Daniel et al., 1997). Research has shown that concentrations of N and P in runoff increase as the manure application rate increases (Edwards and Daniel, 1993a, 1993b) and that runoff N and P concentrations decrease as the interval of time between manure application and the rainfall event increases (Westerman and Overcash, 1980; Edwards and

Daniel, 1993a, 1993b). Incorporation of manure into the soil generally decreases concentrations of N and P in runoff (Mueller et al., 1984), although Nichols et al. (1994) reported that shallow (2–3 cm) incorporation of poultry litter applied to established fescue pasture had no effect on runoff N and P concentrations. Furthermore, incorporation may increase erosion and edge of field losses of particulate P.

With regard to trace metals and organic contaminants in land-applied products, leaching of contaminants to groundwater or transport to surface waters is unlikely with good management of amended soils (Smith, 1996). This assumes application rates have been chosen based on limited metal loadings (less than 40 CFR 503 limits), that trace organics are limited to mg kg⁻¹ levels or less, and that soils are properly limed and runoff and erosion controlled. The solubility of contaminants under these conditions is so low that movement by leaching is very slow, and with control of surface runoff, little export to surface water is expected.

24.6 Recommendations

- Before considering a land-applying by-product material, check with state departments of agriculture and/or environmental divisions to see if the product has been registered or approved for use on land, or is likely to be unsuitable (classified as hazardous waste based on testing or known levels of contaminants).
- 2. By-products have a wide range of properties that affect potential agronomic value and environmental limitations, even within one class of materials. A current, accurate analysis of important chemical properties of the material (nutrient content, pH, liming value, contaminant levels) is the most important piece of information needed to make decisions on use and application rates. Ask the producer to provide this information, or be ready to assume the cost of such an analysis.
- By-products are applied based on one of the following rationales
 - a. as a nutrient source, typically either for N or P
 - b. as a liming agent, determined by the CCE
 - c. as a soil conditioner, in order to increase SOM, waterholding capacity, etc.
 - Application rates should be calculated for nutrient sources and liming material based on (available) nutrients supplied or lime required to reach a target pH. For soil conditioners, specific rates are difficult to determine agronomically, but should be environmentally conservative (see point 4).
- 4. Compute annual loading rates of metals or other contaminants resulting from the application; for biosolids, use the 40 CFR 503 regulations to insure loadings are safe. For other by-products, use 40 CFR 503 limits as guidelines. Be aware of conditions that may make these limits not applicable for low C by-products. Keep accurate records of loadings of metals and nutrients for individual

- fields over time, and do not exceed 40 CFR 503 lifetime cumulative limits.
- Use good management practices on fields to prevent chemical (metals, organics) or microbial (pathogen) losses through runoff or erosion. Follow soil and water conservation practices.
- 6. Soil test for pH and nutrients annually at cooperative extension service or private laboratories. Maintain pH > 6 with lime additions, especially with organic by-products, to minimize metal solubility. Monitor soil P and metal levels, and reduce applications if soil test levels exceed high ratings over time. Check soluble (NO₃⁻ and NH₄⁺) N levels in soils periodically to ensure that excess soluble N is not accumulating in soil.

25.1 Introduction

"For thousands of years, agriculture and tillage were considered synonymous. It was simply not thought possible to grow crops without first tilling the soil before planting and for weed control" (Triplett and Dick, 2008). Indeed, soil tillage as developed over the centuries permitted farmers to grow more and better crops by loosening and mixing soil and controlling weeds. However, with the introduction of herbicide 2,4-D[(2,4-dichlorophenoxy) acetic acid] in 1942 and continued development of new herbicides since then (Unger et al., 2009), the need to mechanically control weeds has slowly, but greatly, declined. Furthermore, the need to prepare seedbeds by plowing and disking has decreased with the increased adoption of no-tillage (NT) since the 1970s. Originally, the use of the moldboard plow was deemed necessary to produce high crop yields, but such plowing (clean tillage) in many cases accelerated erosion by water and wind, organic matter (OM) oxidation, and land degradation. Because of severe erosion, government conservation compliance regulations were implemented in an effort to reduce erosion on highly erodible lands. To meet these regulations and in an attempt to increase profit, many farmers have switched to using conservation tillage (CS) systems, including NT, during the last half century or so. Conservation tillage now is widely recognized as a best management practice that improves soil productivity, reduces runoff and erosion, protects water quality, and improves environmental quality (Sullivan et al., 2008).

Conservation tillage is a broad term used to define any tillage system that has as its primary objective reduction of soil and water losses. The primary reason, however, why farmers in many U.S. regions change from conventional tillage (CT) to some form of CS is to reduce farm input costs and to increase profits (Smart and Bradford, 1996). Secondary reasons include soil and water conservation and insulation of the soil surface from temperature extremes. The use of CS reduces traffic operations, thereby decreasing soil compaction and costs for labor, fuel, tractors, and other equipment. In some cases, however, costs are increased because herbicides cost more than the tillage they replace. Even so,

farmers often adopt the new technology because yields increase at a faster rate than the costs (Bradford and Peterson, 1999).

Timeliness of cultural operations is improved when using CS in many situations. With the development of effective herbicides and improvements in sprayer design (e.g., the hooded sprayer), weed control without tillage can be accomplished, even in subtropical areas of the United States where freezing temperatures seldom occur (Smart and Bradford, 1997). Possibly the most important benefit associated with CS is soil restoration (Langdale et al., 1992; Lal et al., 2004) or in the words of Crovetto (1996), "The great economic advantage of no-till is that low value soils can be brought into higher production without erosion risks."

In this chapter, we discuss the soil science principles of CS, but believe the ultimate goal of CS, especially NT, should be to conserve soil and water while improving food security and environmental quality. If herbicides fail to control weeds, alternative methods such as biological control, crop rotations, or other techniques should be pursued. Where soil compaction becomes a major crop limiting factor, deep-chiseling or zone tillage may be needed to loosen the soil. When surface residue is limited, emergency tillage that can quickly roughen the surface may be needed to control ongoing erosion by wind. Where cold soil temperatures and excess water at spring planting time are problems, it may be necessary to remove most residue from the seeding row in the fall (e.g., while band-applying fertilizer). With time, as soil resilience improves and as farmers become familiar with the total system, soil management becomes easier.

A large number of reports in the literature pertain to the performance of NT relative to that with CT. Most studies pertained to short-term (2-5 years) evaluations of soil and crop parameters. Only few of the studies pertained to long-term trends. Long-term evaluations provide a better overall assessment because many of the benefits or disadvantages develop after several years of using NT. The major benefits of NT agriculture can be more accurately assessed only after NT has been in place for a decade or more. Adoption of NT is an investment in the soils of our future. Adopting CS, particularly NT, has significant agronomic and environmental implications. NT agriculture reduces soil erosion, enhances soil and water quality, sustains crop production, reduces off-site transport of pollutants (e.g., sediment and sediment-bound chemicals), and sequesters soil organic carbon (C), thereby reducing net emissions of greenhouse gases. The organic C enhanced by CS is vital to soil and agricultural sustainability. It improves soil resilience, soil structural stability, microbial processes, water retention, and crop productivity.

25.2 Definitions

The term CS often is used interchangeably with minimum tillage, mulch tillage, reduced tillage, NT planting, and others, thereby creating confusion. We, therefore, begin by defining the various terms used in this chapter. The definitions are from the Glossary of Soil Science Terms (SSSA, 2001) and the Conservation Technology Information Center (Schertz and Becherer, 1994; Hill, 1996). These definitions were also discussed by Bradford and Peterson (1999).

Conservation tillage: Any tillage sequence, the object of which is to minimize or reduce loss of soil and water; operationally, a tillage or tillage and planting combination that leaves a 30% or greater cover of crop residue on the surface.

Conventional tillage: Primary and secondary tillage operations normally performed in preparing a seedbed and/or cultivating for a given crop grown in a given geographical area, usually resulting in <30% cover of crop residue remaining on the surface after completion of the tillage sequence.

No-tillage (or zero tillage; also know as slot planting): A procedure whereby a crop is planted directly into the soil with no primary or secondary tillage since harvest of the previous crop; usually, a special planter is necessary to prepare a narrow, shallow seedbed immediately surrounding the seed being planted. NT is sometimes practiced in combination with subsoiling or in-row chiseling to facilitate seeding and early root growth, whereby the surface residue is left virtually undisturbed, except for a small slot in the path of the subsoiler shank. The soil is left undisturbed, except for nutrient injection and the planting operation. Planters or drills may be equipped with coulters, row cleaners, disk openers, in-row chisels, or rototillers. Weeds are controlled primarily with herbicides. Cultivation may be used for emergency weed control. In essence, NT is the extreme CS method because it results in the least soil disturbance and greatest retention of crop residue on the soil surface.

Ridge tillage: A tillage system in which ridges are reformed atop the planted row by cultivation, and the ensuing row crop is planted into ridges formed in the previous growing season. The soil is left undisturbed from harvest to planting, except for nutrient injection. Planting on ridges is accomplished with planters having sweeps, disk openers, coulters, or row cleaners. Residue is left on the surface between ridges. Weeds are controlled with herbicides and/or by cultivation.

Strip tillage: Tillage operations performed in isolated bands separated by bands of soil remaining essentially undisturbed by the particular tillage equipment.

Mulch tillage: Tillage or preparation of the soil so that plant residue or other materials are left to cover the surface, also known as mulch farming, trash farming, stubble mulch tillage, or plowless farming. Operationally, mulch tillage is a full-width tillage or tillage and planting combination that leaves >30% of the surface covered with crop residue. The soil is disturbed prior to planting. Tillage implements such as chisels, field cultivators, disks, sweeps, or blades are used. Weeds are controlled with herbicides and/or cultivation.

Crop residue management: Disposition of stubble, stalks, and other crop residue (aboveground biomass) by tillage operations to remove them from the soil surface (burying), to partially anchor them in the surface soil while leaving them partially exposed at the surface (mulch tillage), or to leave them at the surface intact or cut into smaller pieces. With regard to crop residue management, CS pertains to using any tillage and planting

Conservation Tillage 25-3

system that retains all or a portion of the previous crop's residue on the soil surface. The goal is to retain adequate crop residue on the surface to control erosion, increase water infiltration and its storage in soil, and decrease soil water evaporation. On some soils, particularly in semiarid regions, crop residue production is limited; therefore, most residue should be retained on the soil surface to provide protection against erosion by water and wind. The portion required depends on other conservation practices that may be included in the farmer's total conservation plan.

25.3 Erosion by Water and Wind

25.3.1 Erosion by Water

Soil erosion by water is a process of particle detachment, transport, and deposition. Sediment must first be detached from the soil mass before it can be transported. In interrill areas, soil is detached by impacting raindrops and transported by sheet flow. Sheet flow concentrates in low areas, thereby forming small channels or rills and detaching and transporting more particles. Reduced erosion by water is achieved, therefore, by limiting either the detachment or transport processes. Complete erosion control seemingly would be achieved by eliminating runoff or reducing it to a flow rate that cannot transport detached particles. Splash erosion that involves detachment and aerial movement of small soil particles due to raindrop impact (SSSA, 2001), however, may still occur when runoff is prevented or reduced to a low rate.

Tillage and surface residue influence soil erosion because they create soil surface conditions and affect surface processes that determine infiltration and runoff rates. Erosion is reduced under CS conditions due to greater crop residue cover that protects the soil surface from raindrop impact, increased consolidation and greater strength of the surface soil layer, increased tortuosity and hydraulic resistance of runoff flow paths, decreased capacity of runoff to detach and transport soil particles, less runoff due to greater infiltration, and increased deposition of sediment in small ponded areas created by surface residue (McGregor et al., 1990; Meyer et al., 1999; Dabney et al., 2004; Wilson et al., 2004; Knapen et al., 2008).

Results given for many studies have shown remarkable reductions in runoff and soil loss when using CS rather than CT. Norton and Brown (1992) reported significantly lower interrill and rill erosion rates in old consolidated ridges in a ridge tillage system as compared with freshly formed ridges. Interrill erosion rates were 40% and 59% lower with older than with freshly formed ridges for Hoytville silty clay (Mollic Ochraqualf) and Rossmoyne silt loam (Aquic Fragiudalf), respectively. For both soils, the rill erosion rate was 72% lower for older ridges than for freshly formed ridges. Interrill soil loss on a moderately well-drained Saybrook silt loam (Typic Argiudoll) under NT for 15 years was reduced to 0.01 kg m⁻² h⁻¹ compared with 2.45 kg m⁻² h⁻¹ for CT when water was applied at an intensity of 100 mm h⁻¹ (Bradford and Huang, 1994). Runoff was 12 mm h⁻¹ for the NT condition and $68\,\text{mm}\ h^{\text{--}1}$ for the tilled soil condition with residue removed. In a study by Andraski et al. (1985), soil loss was consistently 80%–90% less with NT than with CT (moldboard plowing) on Griswold silt loam (Typic Argiudoll) near Arlington, WI. On some soils, however, the smooth consolidated surface with NT may encourage runoff, but the runoff leaving NT fields contains less sediment and sediment-bound chemicals than that leaving plowed fields. Runoff with NT on Pullman clay loam (Torrertic Paleustoll) was 56% greater than with CT in the semiarid environment of northwest Texas, but sediment loss was 54% less with NT than for the tilled treatment (Jones et al., 1994a).

In some cases, sediment loss from NT soils can be practically eliminated as compared with that from plowed soils. Harrold and Edwards (1972) reported negligible soil losses (0.07 Mg ha⁻¹) from a NT watershed having a slope three to four times greater than on nearby plowed watersheds. Soil losses were 7.2 and 50.7 Mg ha-1 from plowed contour- and sloping-row watersheds, respectively, in Ohio. In Nigeria, soil losses were negligible (<0.005 Mg ha⁻¹) from NT watersheds having slopes up to 15% (Rockwood and Lal, 1974). In contrast, soil losses were 16.0 and 3.9 Mg ha⁻¹ from bare fallow and plowed watersheds on 15% slope. Raczkowski et al. (2009) reported a 2.6 Mg ha⁻¹ year⁻¹ soil loss rate with NT for a soil having a 7.0 Mg ha⁻¹ year⁻¹ tolerable loss rate. With CT (chisel plow/disk), soil losses totaled 448 Mg ha⁻¹ for the 6 year study with 397 Mg ha-1 (89%) of the loss occurring during 3 months having multiple storms of high-intensity rainfall. The average loss rate with CT was almost 11 times greater than the tolerable rate for the soil.

NT management often reduces runoff and soil loss due to the accumulation of OM on or near the soil surface, which promotes soil aggregation and improves water infiltration. West et al. (1992) found that NT with residue removed resulted in a 60%–70% decrease in rill erodibility compared with CT systems. They attributed the reduction to increases of organic C from 9.3 to 12.9 g kg⁻¹ and of water-stable aggregates from 50% to 76%, and to greater soil strength due to consolidation. Another study for which soil erosion decreased significantly with NT because of greater aggregation and infiltration was reported by Rhoton et al. (2002). In their study, average annual soil loss was $3.9\,\mathrm{Mg}\,ha^{-1}$ with CT while no soil loss was observed with the NT treatment. Greater aggregate stability and size for NT than for CT soils were reported also by Bruce et al. (1990), Cambardella and Elliott (1993), Drees et al. (1994), Beare et al. (1994a, 1994b), and Lal et al. (1994). The greater structural stability with NT is attributed to increased OM content, surface residue mulch, and biological activity (Doran, 1980; Rhoton et al., 2002). Surface cover provided by crop residue has a major effect on soil erosion by water (Figure 25.1). It is possible to obtain nearly complete surface cover by residue on most soils when using NT and, thereby, achieving maximum control of erosion.

The soil detachment rate due to surface flow in rills is a linear function of hydraulic shear stress. Foster et al. (1980) estimated that the critical shear stress required to initiate erosion in rills in an untilled soil is about 10–15 times greater than that in a freshly tilled soil. Rill erodibility was significantly greater for freshly tilled NT than for undisturbed NT Saybrook silt loam (Typic Argiudoll) in north-central Illinois. The critical shear stress of freshly tilled

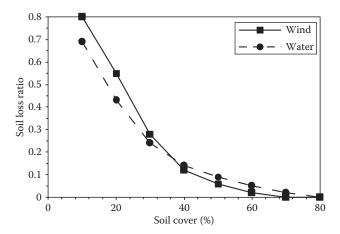

FIGURE 25.1 Relationship between soil loss ratio (loss with cover divided by loss from bare soil) and percentage of surface covered with residues. (Redrawn from Papendick, R.I., J.F. Parr, and R.E. Meyer. 1990. Managing crop residues to optimize crop/livestock production systems for dryland agriculture. Adv. Soil Sci. 13:253–272.)

NT soils is much less than for undisturbed NT soils. The critical shear stress increases with residue removal in NT soils, thus indicating the importance of surface residue for slowing runoff, reducing sediment entrainment by surface flow, and reducing raindrop impact forces due to greater ponding and greater flow depth. If a critical flow rate, slope steepness, or slope length is exceeded, massive rilling may occur in an NT soil, but these critical values are much greater for an NT than for a tilled soil.

Transport of detached particles occurs via surface runoff under both interrill and rill erosion processes. Hence, soil erosion can be reduced by creating soil surface conditions that reduce surface runoff. Runoff from a 0.5 ha watershed on Rayne silt loam (Typic Hapludault) at Coshocton, Ohio, farmed 20 years for continual NT corn (*Zea mays* L.), averaged <2 mm year⁻¹ when average rainfall was >1000 mm year⁻¹ (Edwards et al., 1988). Storms with 1 min rainfall intensities >76 mm h⁻¹ were required to generate surface runoff with NT (Dick et al., 1989). The high infiltration rates were attributed to large macropores resulting from earthworm (*Lumbricus* spp.) activity and old root channels. These macropores are destroyed to the depth of tillage under CT conditions each year. Earthworm populations are greater under high residue (CS) conditions than in CT soil (Kladivko, 1994; Buman et al., 2004).

The effectiveness of crop residue for controlling erosion with any tillage method ultimately depends on the amount of residue retained on the soil surface. Residue retained on the surface obviously is much more effective than incorporated residue for controlling erosion (Wischmeier and Smith, 1978). As indicated earlier, however, in some climates such as in semiarid regions (e.g., southwestern United States) and with some crops [e.g., cotton (*Gossypium hirsutum* L.)], it is difficult to achieve adequate residue cover to protect the soil from erosion by water (Bradford and Peterson, 1999). Also, when a crop such as corn is harvested for silage, too little residue may remain to provide protection against erosion by water.

Residue cover plays an important role in reducing runoff and sediment loss when using NT. On a soil with a loamy sand surface (Plinthic Paledudult-Typic Hapludult complex) in Alabama, Truman et al. (2005) evaluated CT and NT with and without surface residue and with and without soil loosening by paratillage under simulated rainfall conditions. Runoff was greatest from residue-removed, non-paratilled CT plots (58% of rainfall); it was 4% of rainfall from residue-retained, paratilled NT plots. Sediment loss was four times greater with CT than with NT. The use of NT with residue retained along with paratillage to loosen the soil improved soil properties, reduced runoff and soil loss, and resulted in the potential for greater plant available water for row crops. Also in Alabama, runoff from Decatur silt loam (Rhodic Paleudult) varied between times of water application, but it was 34% to 10-fold less from residue-retained, paratilled NT plots than from CT plots (without paratillage and without surface residue). Soil loss was 1.5-5.4 times greater with CT than with other tillage systems (Truman et al., 2003). For that location, NT along with a rye (Secale cereale L.) cover and paratillage was best for reducing runoff and soil losses and for increasing water infiltration and plant available water.

Soils that freeze and thaw may be highly susceptible to erosion in late winter and early spring, especially when the subsurface layer remains frozen and, thereby, limits water flow into or through the soil profile. For a study under simulated rainfall conditions, soil losses were 2.58 and 0.86 kg m⁻² with 0% and 80% surface residue cover, respectively, from boxes inclined at 13% and having a frozen subsurface layer. Losses were 1.24 and 0.58 kg m⁻² with 0% and 80% residue cover from boxes inclined at 5% and soil not frozen (Cruse et al., 2001). Residue cover was considered to be highly important for reducing erosion during the thawing period, especially on steeply sloping soils, and the residue cover was of greater importance when the subsurface was frozen (Cruse et al., 2001). Under field conditions in Minnesota, residue cover was shown to reduce runoff and soil erosion during the spring thaw period (Sharratt et al., 2008). Under many conditions, the use of CS, especially NT, should result in retaining adequate surface residue to reduce soil losses under frozen soil conditions.

25.3.2 Erosion by Wind

The effectiveness of surface residue cover for protecting soil against erosion by wind is similar to its effectiveness for protecting soil against erosion by water (Figure 25.1). In wind tunnel experiments, erosion by wind was reduced 57% with a 20% surface cover and 95% with a 50% cover (Fryrear, 1985). For a sandy Sahelian soil (Psammentic Paleustalk) covered with 1.5 Mg ha⁻¹ of flat millet (*Pennisetum* spp.) stalks, sediment transport by wind was reduced 64%; a cover of 1.0 Mg ha⁻¹ reduced sediment transport 42% (Sterk and Spaan, 1997).

Effectiveness of residue cover for controlling erosion by wind depends on the amount, kind, and orientation of the residue in relation to the soil surface (Siddoway et al., 1965; Lyles and Allison, 1976, 1981). Among seven crops and orientations tested

in a wind tunnel, standing winter wheat (*Triticum aestivum* L.) residue was most effective and flat, randomly positioned sunflower (*Helianthus annuus* L.) stalks were least effective for protection against erosion by wind (Lyles and Allison, 1981). On a weight basis, 5.5 and 8.7 times more standing grain sorghum [*Sorghum bicolor* (L.) Moench] and corn stubble, respectively, was needed to provide the same protection as standing wheat (*Triticum* spp.) stubble (Lyles and Allison, 1976).

Controlling erosion by wind may be unsuccessful with NT where the amount of plant residue produced is low or only a small amount is retained. Continued use of NT for several years, however, usually allows residue to accumulate because of positive feedbacks in the system. For example, residue accumulates over time with continuous NT in a semiarid environment because of its water conservation effect (see next section).

Small grain production (e.g., wheat) in semiarid regions sometimes results in short plants and low plant populations and, therefore, low amounts of plant residue remaining after harvest. When harvesting such crops with combines having cutter-type headers, plants are cut low to the ground, thus leaving short standing residue having low effectiveness for controlling erosion. Harvesting such crops with stripper-header combines has potential to leave taller residue and, therefore, maximize soil conservation while minimizing harvest losses of grain (McMaster et al., 2000; Henry et al., 2008).

Plant material production by crops can be extremely low during dry years. In a study in North Dakota by Merrill et al. (1999), residue yield by spring wheat (*Triticum* spp.) was 0.93 Mg ha⁻¹ in 1988 compared with an average of 3.64 Mg ha⁻¹ in other years (1989–1994). The low amount of residue produced was inadequate to control erosion by wind, even with NT. The spring wheat-fallow (SW-F) system was considered non-sustainable with regard to controlling soil erosion.

Controlling erosion by wind is highly important at the time of crop establishment and early crop growth. On sandy soils of the U.S. southern Great Plains and the Rio Grande Valley of Texas, sandblasting and burying of young cotton and grain sorghum seedlings requires that those crops be reseeded about 2 in 5 years. In the Lower Rio Grande Valley, however, fewer air-borne soil particles are observed under NT than under mulch-tillage conditions (Bradford and Peterson, 1999). In northern Mexico along the Rio Grande River, erosion by wind was much greater under CT than under NT conditions (de Quattro, 1997).

Soil erosion by wind can be greatly reduced by managing residue cover through the use of CS, but data on comparisons of the susceptibility of soils to erosion by wind under specific residue coverings are not available. Modeling of erosion by water and wind under different scenarios of tillage, cropping, and residue management systems can promote an understanding and estimation of soil erosion dynamics on a local and regional basis (van Donk et al., 2008).

Severe erosion by wind often occurs during fallow after wheat when CT is used for the wheat-fallow system in semiarid regions. Schillinger (2001) in the U.S. Pacific Northwest found that using minimum tillage and delayed minimum tillage systems significantly increased surface residue and clod retention, which improved control of erosion by wind.

The severe erosion in the Pacific Northwest (in eastern Washington and Oregon) results in air-borne soil particles that cause major concern regarding air quality (Saxton, 1995; Janosky et al., 2002). Erosion during the dust mulch (CT) fallow phase after winter wheat is the major source of the air-borne particles (Thorne et al., 2003). By maintaining a soil surface cover in spring and fall when the potential for erosion was high, cropping of spring cereals under NT conditions reduced the susceptibility to erosion as compared with the winter wheat-fallow system. Cover with NT results from both plant canopy and residue maintained on the soil surface; cover is the dominant factor regarding the reduction in soil erodibility. Adoption of spring cropping under NT conditions would significantly reduce erosion in crop-fallow areas (Thorne et al., 2003).

25.4 Water Conservation

Residue management and CS effects on soil water storage and use are highly dependent on climate and soil type. Soil water content generally is greater under NT than under CT conditions (Smika, 1976; Dickey et al., 1983; Unger, 1984; Díaz-Zorita et al., 2004). Greater soil water contents with NT result from increased infiltration and reduced evaporation with adequate residue cover. In contrast, greater water loss occurs from tilled soils because tillage exposes moist soil to the atmosphere, thereby increasing evaporative water losses.

In some situations, using NT has resulted in lower infiltration rates due to the development of a highly consolidated soil surface. Such was the case on a sandy loam Alfisol in Nigeria. Differences were not significant under CT and minimum tillage conditions for infiltration rate or accumulated infiltration, but were greater than with NT (Akinyemi and Adedeji, 2004). Apparently, benefits of surface residue remaining with NT regarding accumulative infiltration were negated on the consolidated sandy loam.

In the United States, the relative benefits of residue management for conserving water become greater when going from the wetter, more humid regions into the drier, semiarid regions. In humid or subhumid regions, additional soil water resulting from CS has increased crop yields relative to those obtained with CT, particularly when soil water becomes limited during the growing season. The water conservation benefits of CS normally decrease the adverse effects of short midseason droughts. In mid-summer, soil surface temperatures often are several degrees cooler under plant residue than those of bare surfaces because the surface residue insulates the soil surface against solar radiant energy. As a result, soil water evaporation is less from the residue-covered soil (Lascano and Baumhardt, 1996).

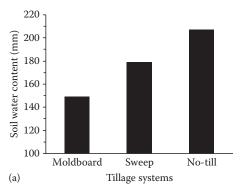

The water conservation benefits of CS have resulted in significant crop growth and yield increases relative to those obtained when using CT. In a study conducted in the Upper Piedmont region of North Carolina, corn and soybean (*Glycine max* L.) yields were 32% and 43% greater, respectively, with NT than with CT on a Pacolet sandy clay loam (Typic Hapludult) (Wagger and

Denton, 1989). The crusted soil surface with CT limited infiltration, thus resulting in lower soil water contents than with NT. In a study in the Lower Piedmont of North Carolina, total wateruse efficiency (units of crop produced per unit of water used) for corn grain production increased from 0.18 Mg ha⁻¹ cm⁻¹ with CT to 0.22 Mg ha⁻¹ cm⁻¹ with NT in the fourth study year on a Hiwassee clay loam (Rhodic Kanhapludult) (Wagger and Cassel, 1993). For corn silage, water-use efficiency was 0.29 Mg ha⁻¹ cm⁻¹ with CT and 0.34 Mg ha⁻¹ cm⁻¹ with NT. Yields of both corn grain and silage were about 20% greater with NT than with CT.

In some cases, cooler and wetter soils can lead to slower crop development and lower yields. On a very poorly drained Hoytville silty clay loam (Mollic Ochraqualf) in Ohio, 10 year average yields of continual corn were 13% lower with NT than with plowed treatments (van Doren et al., 1976). For a study in Michigan where no residue, root only residue, and total wheat residue treatments were compared for NT corn production, soil water content was greater and soil temperature was lower with the total residue treatment (Kravchenko and Thelen, 2007). Residue mulch has mixed effects on crop yields, depending on soil nutrient availability and soil temperature fluctuations. In Colorado, lower grain yield of irrigated corn with NT than with CT probably results from slow early growth and delayed tasseling due to cooler springtime soil temperatures with NT (Halvorson et al., 2006).

In semiarid regions where water availability is a greater limiting factor for plant growth, increased water conservation with NT normally produces greater crop yields. Water content in a silty clay loam (Udic Boroll) in North Central Alberta, Canada, was greater with NT than with CT (Nyborg and Malhi, 1989). In Australia, greater and deeper water movement occurred with NT than with CT in Hermitage clay (Udic Pellustert) (Dalal, 1989). Infiltration on seven soils of the Pacific Northwest was 30% greater under NT or grass conditions than under CT conditions (Wuest et al., 2006), thereby providing for greater water availability for crop use. Over winter water infiltration and soil water storage in eastern Washington, however, are similar with CS and CT where stubble from the previous wheat crop is undisturbed and left standing (Kennedy and Schillinger, 2006).

The increased amount of water stored in soil by retaining crop residue on the surface is highly effective for increasing grain yields of subsequent crops. At Bushland, Texas, soil water contents were determined at grain sorghum planting after fallow following wheat harvest. The water contents and sorghum grain yields are shown in Figure 25.2a and b, respectively. The grain yield increases were 7 and 10 kg mm⁻¹ of additional water stored with the sweep tillage and NT treatments, respectively, as compared with the moldboard treatment (Unger, 1984). The greater response with NT than with sweep tillage indicates an additional water conservation benefit due to the greater amounts of residue present with NT during the growing season. For an irrigated wheat-dryland grain sorghum study at Bushland, soil water storage efficiencies during fallow after wheat were 35% with NT and 15% with disk tillage (Unger and Wiese, 1979). Average grain yields of dryland grain sorghum planted after fallow were 3.14 and 1.93 Mg ha⁻¹ with the respective treatments.

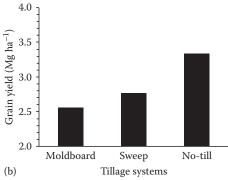

FIGURE 25.2 Soil water contents at planting (a) and grain yields of sorghum (b) as affected by different tillage systems at Bushland, Texas. All differences due to tillage systems were significant. (Adapted from Unger, P.W. 1984. Tillage and residue effects on wheat, sorghum, and sunflower grown in rotation. Soil Sci. Soc. Am. J. 48:885–891.)

Surface residue maintained by using stubble mulching in U.S. Great Plains wheat-fallow systems increased precipitation use efficiency from 0.09 to 0.14 Mg ha⁻¹ cm⁻¹ (Greb, 1979). Conversion to NT, however, did not lead to further increases in the productivity of wheat-fallow systems. Other studies have shown that water is stored more rapidly with NT than with tilled systems during the early part of the fallow period, and that NT fallow systems usually result in as much stored water by early spring as when fallowing is done for an additional 3 months with tilled systems (Peterson et al., 1996). It has been clearly demonstrated from North Dakota to Texas that adding spring crops to the cropping system is the only way to more efficiently use the extra precipitation stored with NT. Conversion from wheat-fallow to systems such as wheat-corn (or sorghum)-fallow increased water use efficiency from 0.06 Mg ha-1 cm-1 with wheat-fallow to 0.08 Mg ha⁻¹ cm⁻¹ for wheat-corn (or sorghum)-fallow (Peterson et al., 1996). The more intensive cropping (IC) systems not only resulted in a 43% increase in water use efficiency, but also greatly reduced the potential for soil erosion by water and wind. Tanaka and Anderson (1997) observed that NT and minimum tillage stored 12% more water and increased precipitation capture by 16% compared with mulch tillage in wheat production systems on a Williams loam (Typic Argiboroll) near Sidney, Montana.

Precipitation amount is not the only issue involved in water conservation with NT. Its distribution is equally important when comparing effectiveness of NT in semiarid regions. In the

Pacific Northwest where average annual precipitation is 290 mm, greater water loss occurs during the fallow period with NT than with CT (Schillinger and Bolton, 1993). The major reason for different results with NT fallow in the Great Plains versus results in the Pacific Northwest is the long dry period (no summer rainfall) in the Pacific Northwest compared with mostly summer rainfall in the Great Plains. Hammel (1995) reported that depth and amount of water extracted by winter wheat grown under NT conditions were considerably less than with CT (mold-board plow) and minimum tillage (chisel plow) systems in the Pacific Northwest. The decrease may have resulted from higher surface layer impedance and possibly due to root diseases (Hammel, 1995).

In Oklahoma, Dao (1993) found water storage to be greater with NT than with tilled systems for continual wheat. In the northern Great Plains, Tanaka (1989) found that the response of spring wheat to tillage treatments varies yearly, depending on soil water storage during fallow and early spring temperatures. He pointed out that during years with little soil water storage after fallow and above average early spring temperatures, using chemical fallow (essentially NT) results in greater spring wheat yields than using stubble-mulch fallow. However, during years with abundant soil water storage after fallow and below-average spring temperatures, use of stubble-mulch fallow produces more spring wheat than use of chemical fallow. Based on a 4 year average, water use efficiency was greater with stubble-mulch and reduced tillage than with chemical fallow.

Soil desiccation that results from dry and strong winter winds that occur from south Texas to western Canada is reduced by the presence of surface residue. In south Texas and northern Mexico, greater soil water contents at planting under NT conditions often result in adequate seedling emergence as compared with no germination under other conditions (Bradford and Peterson, 1999). Conservation tillage practices that increase water storage have been developed for cotton in the central Texas High Plains (Harman et al., 1989) and for dryland grain sorghum at Bushland, Texas (Unger, 1991; Jones et al., 1994b).

During prolonged dry periods in the U.S. semiarid regions, cultivated soils and NT soils will dry out with time and reach the same water content. In some instances, the water content of upper soil layers even may become lower in NT than in CT soils because of capillary drying with NT. Surface cultivation under CT conditions decreases such drying in some soils (Bradford and Peterson, 1999).

A possible negative effect of greater water infiltration and higher soil water contents with CS is the potential for increasing saline seep problems on some soils. Saline seeps develop where relatively large amounts of water enter soils that have a relatively impermeable subsoil. As a result, the water table rises and water flows and seeps to the surface at down-slope sites, carrying with it dissolved salts. According to Halvorson (A. Halvorson, personal communication, 2009), the solution to the saline seep problem is more intensive dryland cropping to utilize the precipitation more efficiently.

Fresh water availability is becoming an increasingly important worldwide issue (Unger and Howell, 1999). It is a major

agricultural concern where water is naturally limited and where the increasing needs of other users often clash with agriculture for available supplies (Rothfeder, 2001; Levy, 2003; Kuhn et al., 2007). Improved water conservation, therefore, is becoming increasingly important for agriculture and for society as a whole so that adequate water will be available for all users. Improved water conservation is possible by increased adoption of CS, which is important for rainfed and irrigated crop production. Greater soil water storage with CS can reduce irrigation requirements (Sullivan et al., 2007).

25.5 Residue Management and Decomposition

Unlike with CT, the main goal with CS is to minimize residue incorporation into the soil. For CS systems, farm implements are specifically designed to leave the maximum amount of residue on the soil surface, whereas for plow systems, the intent often is to incorporate the residue as quickly as possible to minimize problems associated with subsequent tillage operations. Residue amounts remaining on the surface after one pass with various implements are presented in Table 25.1. Implements such

TABLE 25.1 Percentages of Surface Residue Cover Remaining after One Pass with Various Implements

Tillage and Planting Implements	Percentages
Moldboard plow	0-10
Machines that fracture soil	70-90
Chisel plows	
Straight points	60-80
Twisted points	50-70
Sweeps and field cultivators	60-90
Disk machines	
One-way disk	55-80
Tandem or offset disk	
25 cm or greater blade spacing	25-50
18-25 cm blade spacing	30-70
Harrows and packers	60-95
Row cultivators	
Sweeps	75-90
Finger wheel cultivator	65-75
Rolling disk cultivator	45-55
Ridge-till cultivator	20-40
Drills and planters	60-95
Natural weathering	
Over-winter following summer harvest of small grain	70-90
Over-winter following fall harvest of summer crop	80-95

Effects of tillage sequences on residues, soil cloddiness, weed control, and wheat yield. Agron. J. 57:52–55; Hill, P.R., K.J. Eck, and J.R. Wilcox. 1994. Managing crop residue with farm equipment. Agronomy Guide AY-280. Purdue University, West Lafayette, IN; Bradford, J.M., and G.A. Peterson. 1999. Conservation tillage, p. G-247–G-270. In M.E. Sumner (ed.-in-chief) Handbook of soil science. CRC Press, Boca Raton, FL.

as the moldboard plow and the tandem disk that invert and/or vigorously stir the soil leave less than 5% and 60% of the residue on the surface, respectively. Repeated passes with a tandem disk result in essentially no residue on the surface. In contrast, slicing-action implements such as chisels and sweep plows leave 50%–90% and 85%–90% of the residue, respectively. Managers thus have some control over residue cover, depending on the implement they use. NT relies on herbicidal weed control and no primary tillage; therefore, it provides for maximum possible surface residue cover.

Residue decomposition rates are affected directly by the amount of residue incorporation that occurs (Schomberg et al., 1994). Both surface and buried residue immobilized N, but surface residue immobilized N three times longer than buried residue, which reflects the residue decomposition status. Maximum decomposition rates occurred when residue was completely incorporated into the soil; slower decomposition occurred with NT. In the study by Schomberg et al. (1994), grain sorghum and wheat residue decomposed at about the same rate, and decomposition rates were highest under the wettest regimes. Residue decomposition rates with NT and other CS systems were highly dependent on surface soil water content and temperature. Decomposition rates were highest when soil temperatures were between 20°C and 30°C and the water content was near field capacity just under the residue cover.

Decomposition of surface residue is maximized in climatic regions where atmospheric water demand is low, relative humidity is high, warm temperatures prevail, and growing seasons are long. Peterson et al. (1995), working across a potential evapotranspiration (ET) gradient in Colorado under NT conditions, showed that surface residue loss from corn planting to harvest varied from 32% in the lowest to 62% in the highest ET zone. Higher temperatures in the high ET zone and the longer warm season promoted faster decomposition despite the drier conditions. Obviously, temperature controlled decomposition more than the relative humidity of the air at the soil surface.

The objective of CS farming is to maintain surface residue cover throughout the growing season, but especially during the preplant and seedling stages of a crop cycle because the soil is most vulnerable to erosion by either wind or water at those times. When the crop canopy provides adequate cover, residue cover becomes less important until after crop harvest. The importance of a residue cover after harvest depends on the particular climate. With high erosion potential after harvest, obviously residue cover is needed to help control erosion. On an average, a crop such as soybean leaves less cover than a crop such as corn. Furthermore, soybean residue that has a favorable C:N ratio degrades 20%–30% over winter whereas corn stalk residue that has a less favorable C:N ratio degrades 5%–20% over winter (Hill et al., 1994).

Planting equipment being used often dictates how much tillage is needed for seedbed preparation. Prior to the advent of CS, seedbeds had to be free of residue to ensure proper planter operation. Now, NT planters for both small grain and row crops are commercially available. Those planters minimally disturb the soil and leave most residue on the surface (Table 25.1).

25.6 Biological Activity

Biological activity generally is greater in CS than in CT soils. First, with CS, especially NT, there is a continuous and uniform supply of C as an energy source for organisms because the residue is not introduced all at once as is the case with CT. Secondly, the soil water content remains higher longer with CS, thereby allowing for more organism activity. Blevins et al. (1984) summarized the NT influence on soil biology.

High residue levels favor the activity of macroorganisms such as earthworms. Results of the following studies illustrate the large differences between NT and CT soils as well as the effects of crop residue management on earthworm populations. Kladivko et al. (1997) observed more earthworms in NT than in CT soils in paired sites under corn-soybean rotations across Indiana and Illinois. Similarly, Johnson-Maynard et al. (2007) found that when averaged across spring and summer seasons, NT soils had more earthworms (104 m⁻²) than CT soils (27 m⁻²) under spring pea, wheat, and barley in Palouse silt loam (Pachic Ultic Haploxeroll) in Idaho. In Ohio, Blanco-Canqui and Lal (2007a) reported that the number of earthworms decreased with a systematic increase in corn stover removal from Rayne silt loam (Typic Hapludult), Celina silt loam (Aquic Hapludalfs), and Hoytville clay loam (Mollic Epiaqualfs). In silt loams, earthworms averaged $78\,m^{-2}$ in plots with $<\!25\%$ of stover removed and 32 m⁻² in plots with >25% of stover removed, whereas 100% stover removal eliminated earthworms from a clayey soil.

Earthworm activity creates soil physical conditions that favor water infiltration. Runoff was <2 and 700 mm year-1 from NT and CT watersheds, respectively, used for continual corn production for 20 years in an area that receives over 1000 mm of precipitation annually (Edwards et al., 1988). The difference was attributed to earthworm burrows in the NT watershed. Use of NT increases earthworm populations and allows their burrows to remain intact from season to season, thus providing continuous pathways for water infiltration. Furthermore, earthworm burrow diameters are much larger than the usual size of soil pores and, therefore, promote rapid intake of large volumes of water. This water is immediately transmitted past the surface soil and is stored at a depth from which evaporation is slight. Rainstorms causing the most flow in burrows were high intensity, short duration events (Edwards et al., 1989), which indicates that burrows would enhance seasonal water infiltration substantially in regions where high intensity thunderstorms are prevalent. Trojan and Linden (1994) showed that earthworm activity could more than double water penetration into NT soil as compared with CT soil under high intensity rainfall conditions.

Greater water infiltration due to earthworm activity decreases the potential for erosion and rapidly transfers water to greater depths, thereby enhancing water storage in the profile. Possible negative aspects of this rapid transfer are soluble fertilizer and pesticide movement to depths where they are less effective for their intended purposes (Hawkins et al., 2008) and groundwater contamination.

Biological activity at the microscale is also affected greatly by adoption of reduced tillage and NT systems, and these effects can be positive or negative. On the positive side, Dick (1984) observed increased activity of many enzymes in the top 7.5 cm of soil after 18 years of NT in Ohio, which was related to soil organic C contents. Furthermore, the herbicides and pesticides used for NT management did not appear to adversely affect enzyme activity. Other evidence for increased biological activity under NT was provided by Staley et al. (1988), who reported that soil biomass-C reached a maximum in surface soil after just 1 year under NT. Biomass-C approached levels found in pasture environments, and equilibrated in 10 years at a level 30% greater than with CT.

Processes that involve N are excellent indicators of microbiological activity and several authors have made interesting observations regarding contrasts between CS and CT systems. For example, Lamb et al. (1987) showed that N₂ fixation potentials in wetter NT soils were twofold greater than in drier plowed soils. Although the quantities of N₂ fixed were small (0.33 kg ha⁻¹ year⁻¹), the data show the distinct difference that persists in microbial environments with NT as compared with those with CT. The increased microbial biomass present under NT conditions reduced potential N losses during periods of low crop demand because the N was incorporated into organic compounds that were less subject to loss through leaching and denitrification (Bremer and van Kessel, 1992). Wood et al. (1990) reported that adopting NT after long-term use of CT quickly increased the amount of surface residue and of potentially mineralizable N. When they used more intense cropping systems in conjunction with NT, they obtained the highest N mineralization.

Possible negative effects of microbial activity on soil-plant systems include greater loss of N from urea fertilizers, greater denitrification, and production of phytotoxic compounds. Dick et al. (1991) showed that soils with a 25 year history of NT had increased urease activity at the surface, making ureabased fertilizers more susceptible to N volatilization losses. Rice and Smith (1982) showed that the denitrification potential increased under NT because of the more conducive environment provided by the large amounts of C at the soil surface, which resulted in the high biological activity, and the wetter soil conditions under the residue cover.

Phytotoxic compounds synthesized by microorganisms during residue decomposition were identified many years ago. NT environments have regenerated interest in these compounds and in the processes involved in their production. The slower residue decomposition, the prolonged production period, and the colder temperatures in the soil or at the soil surface and very near the emerging plant seedlings create potentially enhanced phytotoxicity problems under NT conditions. Buchanan and Kin (1993) clearly demonstrated that the decomposition period with NT was longer than with tillage systems. Working in a warm North Carolina environment, they found that 45% and 20% of the C remained under NT and CT systems, respectively, after 50 weeks. The results were similar for wheat and soybean stalk

residue. Cochran et al. (1977) demonstrated that surface residue of lentil (*Lens culinaris*), pea (*Pisum* spp.), wheat, barley, and bluegrass (*Poa* spp.) all produced phytotoxic materials at some point during the spring season. Toxicities were worst when wet weather and low temperatures prevailed. Lentil and pea materials were more toxic to wheat seedlings than the other materials, but toxin production fortunately was short-lived. Martin et al. (1990) found that microbially synthesized phytotoxic materials from corn residue were more damaging to corn seedlings than were the byproducts of soybean and oat (*Avena sativa* L.) residue decomposition. Corn planted back into corn residue, therefore, would be more prone to phytotoxin damage than corn planted into soybean or oat residue. These findings illustrate that to avoid potential seedling damage, it may be more important to use crop rotations when using NT than when using CT systems.

25.7 Carbon Dynamics and Sequestration in No-Tillage

In contrast to agriculture with tillage, NT soil management greatly alters the C cycle because plant residue C is added to the soil in a different manner. The traditional moldboard plow system is the antithesis of NT. Moldboard plowing inverts and incorporates most or all residue of the previous crop into the soil in one operation. In such case, microbes responsible for the residue decomposition process are stimulated by the instantaneous addition of large amounts of organic C. No matter what system is used, however, decomposition rates are controlled by soil water conditions, soil temperature, and inorganic N supply. If the water content is above the wilting point and the temperature is above 4°C, inorganic N supply limits decomposition. In tilled systems, if appropriate amounts of N fertilizer are added, soil organisms can complete decomposition of the incorporated crop residue and roots in the surface soil layer within a few months after plowing. Often, the surface soil is disked before plowing and/or the crop residue is shredded to enhance farm implement function, which creates more residue surface area for soil organisms and hastens the decomposition rate. Large quantities of CO₂ evolve from soils shortly after plowing. Soils usually are tilled several more times after plowing to prepare a fine, firm seedbed for planting. These operations stir the soil and residue mixture, and further stimulate decomposition of the organic materials if the soil contains adequate water. Tillage, however, also hastens soil drying, which may retard decomposition if no rainfall or irrigation occurs.

Continued use of any type of inversion tillage for a long time decreases soil aggregate size, which results in organisms having access to C that once was physically inaccessible within the larger aggregates. Therefore, organic C that literally required centuries to be stored is released as CO₂ within a few years. For example, when temperate-zone soils of North America were first cultivated, as much as 10⁹ Mg of C were released as CO₂ (Paustian et al., 1997). Intensive tillage accelerates release of CO₂ and thereby increases organic C losses (Blanco and Lal, 2008). On Barnes

loam (Udic Haploboroll) in west central Minnesota, Reicosky and Archer (2007) observed that the CO_2 release from CT soils was consistently greater than from NT soils under spring wheat, particularly immediately following tillage. Deep and frequent tillage increases the release of CO_2 relative to shallow tillage. Retaining crop residue after harvest and reducing tillage depth are strategies to enhance organic C sequestration and reduce emissions of greenhouse gases.

When soils that have been managed with maximum tillage such as by moldboard plowing are converted to NT, a dramatic change occurs in the way organic C is introduced into the soil system, both in terms of timing and position. Furthermore, soil under NT management remains wetter for longer periods. The new system (NT) results in little or no mixing of residue with the soil. Crop residue remains on the surface and decomposition occurs much more slowly than under tillage conditions because much less surface area of residue is exposed to soil organisms, even if the producer shreds the residue. Roots at shallow soil depths also remain basically intact, again reducing their area exposed to decomposition. Soil surfaces with NT are generally moist enough, especially in the spring and early summer, so that water availability does not limit decomposition. The residue cover, however, keeps the soil cooler longer than for a bare surface soil, especially in northern latitudes, thus slowing decomposition.

Under NT conditions, N supply is more limiting for decomposition because the organisms have access only to the inorganic N in a much smaller soil volume than in a tilled system. Obviously, root mass decomposers have access to more N than surface residue decomposers, but overall residue decomposition is delayed with NT relative to that in a tilled soil.

After 5–10 years, the amount of surface residue in an NT system appears to reach equilibrium for a given soil and climate combination (Sherrod et al., 1996). Resident residue levels increase more in cooler than in warmer climates due to slower decomposition rates in the former. Within climatic zones, soil types also affect residue levels. Excessively drained soils have lower residue levels relative to well-drained soils primarily because less biomass is produced. At the other extreme, wetter soils have greater residue levels because biomass production generally is high and because the cooler soil environment in the wet soil delays decomposition, which, in turn, is accentuated by the heavy residue cover.

Generally speaking, the total C sequestered in surface residue plus the organic C in the uppermost soil layer (0–5 cm depth) is higher with NT than with the same soil under tilled conditions. Furthermore, substantial amounts of C still reside as crop residue in the upper 2.5 cm of soil. Ortega (1995) found residue C amounts within the upper 2.5 cm of NT soil equal to that present on the soil surface and Dell et al. (2008) found about 50% more C in particulate and mineral-associated pools in the upper 5 cm of NT soils than of CT soils.

Soil organic C tends to increase with NT relative to that with tilled systems, but the increase rate is slow and usually confined to the upper soil layers with little effect on deeper layers

(Dick, 1983; Potter et al., 1998). Changes in soil C after 18 years were 0% to -11% with NT, -12% to -23% for minimum tillage, and -14% to -23% for CT (Dick, 1983). Organic P also was greater in surface soil layers with NT than with tillage. Wood and Edwards (1992) found that NT relative to CT resulted in C and N concentrations after 10 years that were 67% and 66% greater, respectively, than those with plow tillage at the 0-10 cm depth. Macroaggregates (>250 mm) under NT were more numerous and more stable than those under CT, probably due to greater biological activity under NT conditions. Microbiological activity was more episodic in the tilled system, which had a drier surface soil than NT. CT also caused more physical disruption coupled with less production of aggregate-stabilizing materials. For a drier climate (eastern Colorado), Wood et al. (1991) concluded that higher equilibrium levels of soil C and N could be maintained by increasing cropping intensity, which increased C input to the system. These changes were measurable even after only 4 years of NT. Less inorganic NO₃-N was present in the intensive system, indicating that the N loss due to leaching or denitrification was reduced.

Data from Colorado show that with some NT systems, OM contents have increased in the upper 5cm of soil, but have declined in the 5–10cm depth. The net result for the 0–10cm depth generally was a decline after 7 years of NT, especially in systems that include fallow. Under climate and soil conditions that permit continual cropping, adoption of NT is likely to increase soil OM much more. This means that the more humid the climate (high precipitation coupled with low potential ET), the greater the probability that NT will promote soil OM accumulation. Conversely, under climates with low precipitation and high ET that usually require fallow periods in the cropping systems, there would be less chance of increasing soil OM; and net losses of C may occur, even under NT management, because of less plant material production under such conditions.

NT adoption promotes restoration of some of the C lost when soils were broken from their native condition. Potential C sequestration, however, can be small and slow relative to the losses from the original soil OM level, depending on soil, management, and climate. It will take years of NT farming to increase soil C because the amounts of available N and P required to provide the correct C:N and C:P ratio for C sequestration are limited. For example, producers usually apply adequate N for the crop, but plan to leave no excess in the soil system. Therefore, little N is available to balance the high C input from crop residue. The same situation can occur with P, especially in soils with low P availability. Paustian et al. (1997) provided an excellent summary of tillage effects on soil OM. They concluded that reduction in tillage, and especially using NT, provided an environment conducive to C storage in soils. Soil organic C storage is generally greater with NT than with CT at the 0-5 cm depth (West and Post, 2002). In a few cases, where NT reduces biomass production compared with CT, there may be no differences between NT and CT.

What is the net effect of NT on the C cycle? It is the amount sequestered in the soil. Carbon sequestration in soil has received

much attention in recent years because of the possible effect that increasing atmospheric CO2 levels may have on global climate change. More soil organic C can be sequestered by using reduced tillage and NT in combination with diversified cropping systems than by using CT. It is estimated that about 60% of organic C has been lost due to intensive plowing, monocropping, simplified crop rotations, and short-sighted management systems (IPCC, 1996; Benjamin et al., 2007). These losses make up nearly 23% of the total greenhouse gas emissions in the atmosphere (Lal, 2004). Reducing or eliminating tillage is a strategy to restore the organic C pool. For example, NT, in addition to providing many other benefits, can enhance soil organic C sequestration. Across five soils in Kansas, McVay et al. (2006) showed that NT management resulted in more soil C at the 0-5 cm depth than CT management. The increase of residue-derived C in a silt loam in Minnesota was 2.3 times higher with NT than with CT or chiselplowing (Allmaras et al., 2004).

NT is superior to CT for storing C in soil. In most cases, however, organic C in NT soils is concentrated near the surface (West and Post, 2002). The marked stratification of organic C in NT soils is partly due to surface residue mulching. The soil organic C with NT can be higher at the 0–5 cm depth and lower below this depth compared with plowed soils. Furthermore, substantial amounts of C still reside as crop residue in the upper 2.5 cm of soil. Ortega (1995) found residue C amounts within the upper 2.5 cm of NT soil equal to that present on the soil surface and Dell et al. (2008) found about 50% more C in particulate and mineral associated pools in the upper 5 cm of NT soils than in CT soils.

The difference in total organic C between NT and plowed soil profiles may not be significant if there is considerable stratification. It is important to note that organic C stored in deeper layers is important to long-term C sequestration (Lorenz and Lal, 2005). The organic C near the surface layers is subject to abrupt fluctuations in soil temperature and soil water content, which causes rapid mineralization of soil organic materials.

The NT impacts on C sequestration must be characterized for the entire soil profile and not only for shallow surface soil (<20 cm depth) (West and Post, 2002). Plant roots of most crops often extend to a 50 cm depth (Qin et al., 2006), which is much deeper than the typical soil sampling depth for organic C characterization (West and Post, 2002). Plant roots in plowed soils may penetrate to greater depths than in NT soils because of relatively loose soil following tillage. Recently, some researchers have argued that the greater C sequestration in NT systems reported in many studies may be simply due to shallow sampling protocol that biases the results (Baker et al., 2007). At this point, the limited information on organic C distribution for the whole soil profile hinders our ability to conclusively state the benefits of NT farming to sequester C at lower profile depths.

A study conducted under on-farm conditions in the eastern United states by Christopher et al. (2009) showed that organic C with 5–35 years NT systems was not greater than with CT systems in most soils at the 0–5 cm depth. Total organic C in the profile with NT and CT did not differ in 8 of the 12 soils.

It was actually greater with CT than with NT in three soils after 8, 15, and 30 years of NT management. For a similar on-farm study for the same temperate region, Blanco-Canqui and Lal (2008) observed that NT management increased organic C concentration over CT in 5 out of 11 soils, but the increases were significant only at the 0–5 cm depth. Beneficial effects of NT for increasing organic C pools tend to disappear with increases in soil depth.

Impacts of NT farming on organic C can thus be variable and soil-specific (VandenBygaart et al., 2003). Length of NT management, degree of soil erosion, crop grown, and residue incorporation with CT are among the factors that cause differences between NT and CT. Increases in organic C with NT often are more pronounced with long-term (>10 years) management and for erosion prone soils. Indeed, NT farming may favor greater organic C storage in sloping terrains and soils with low clay content. NT benefits for increasing organic C concentrations, particularly at lower profile depths, are complex and should not be generalized for all soils.

25.8 Biofuel (Cellulosic) Production Implications

Crop residue retained on the soil surface greatly reduces the potential for soil erosion by wind and water (Figure 25.1) and enhances water conservation under many conditions. Such residue retention, therefore, is highly important for conserving the soil resource base to maintain its sustainability for crop production and to enhance production by effectively using the conserved water for greater crop production for an everincreasing world population. These benefits generally increase with increases in the amounts of residue retained on the surface, as discussed in previous sections. Removing even some residue, at least from some soils, therefore, would negate the conditions essential for sustained or improved soil and water conservation and crop production.

One of the main differences between CS and plow tillage (CT) is that most crop residue remains on the soil surface when using CS, thereby enhancing soil and water conservation. Today, however, there are many competing uses for crop residue including soil and water conservation, animal feed, industrial raw material, and as feedstock for cellulosic ethanol production. Particularly, producing biofuel from crop residue is generating a lot of interest (Perlack et al., 2005). A number of commercial-scale cellulosic ethanol plants are being built in the United States to produce the second generation of biofuel (USDOE, 2007). Production of ethanol from cellulosic plant materials is projected to increase exponentially in the near future as concerns over increased food prices may slow ethanol production from grain. At present, corn stover is the main candidate as cellulosic feedstock for biofuel production (Graham et al., 2007). Residue of crops such as wheat and sorghum is also being considered as feedstock for biofuel as technologies for cellulosic conversion progress (Sarath et al., 2008). Production of cellulosic ethanol from renewable energy sources is important and should be pursued. But removing crop residue as biofuel feedstock must be objectively examined and contrasted against its positive and negative impacts on soil conditions, crop production, and environmental quality. Dedicated energy crops (e.g., warm season grasses and fast-growing woody plants) are potential alternatives to crop residue removal.

25.8.1 Negative Aspects of Crop Residue Removal

Removal of crop residue can have more negative than positive impacts in the long term for conserving soil and water resources (Wilhelm et al., 2007). Although sometimes dubbed as "low-cost waste," crop residue is a valuable commodity. Indiscriminate removal of crop residue is not advisable particularly in semiarid regions with low and variable precipitation and biomass production. Crop residue mulch is important for precipitation capture and storage, and water use efficiency. By increasing soil erosion, residue removal can also accelerate losses of nutrients in runoff, thereby further increasing risks of non-point source pollution of downstream water sources such as ponds, lakes, rivers, and streams. Sediment and sediment-borne chemicals (e.g., fertilizers and pesticides) are the major pollutants in runoff. Total N and total P transport in runoff often increases with increases in crop residue removal (Lindstrom, 1986; Blanco-Canqui et al., 2009). Residue removal can also increase soil susceptibility to erosion by wind by leaving the soil partially or completely unprotected. Soils under NT conditions can be as susceptible to erosion by wind as CT soils unless adequate residue cover is maintained on the surface.

Crop residue mulch reduces the susceptibility of the surface soil to compaction by buffering impacting raindrops and traffic. Residue mulched soils are more resilient than unmulched soils (Wilhelm et al., 2004). Residue cover also reduces fluctuations in soil temperature and wetting and drying cycles. Soil aggregate stability, water infiltration, water retention, saturated hydraulic conductivity, macroporosity, and biological activity decrease, whereas soil cone index and bulk density increase with increases in crop residue removal (Karlen et al., 1994; Blanco-Canqui and Lal, 2007a).

Crop residue removal reduces soil organic C because residue contains about 45% C. Removal of crop residue for alternative uses reduces not only organic C, but also plant nutrient pools. Nutrients also may be lost via increased erosion (Blanco-Canqui et al., 2009). The magnitude of losses depends on soil and climatic conditions. For example, losses of organic C pools in some soils increase linearly with increasing removal rates of corn stover (Karlen et al., 1994; Clapp et al., 2000). Blanco-Canqui and Lal (2007a) observed that removal of corn stover from long-term NT soils decreased organic C pools in sloping and erosion-prone soils, but had little or no effects on nearly level, clayey, and cold soils 3 years after residue removal.

Crop residue removal influences crop production because it reduces plant available water and causes abrupt fluctuations in soil surface temperature. Crop residue is a source of soil OM and essential plant nutrients and thus its removal can reduce the supply of vital nutrients. On a silty clay loam in Nebraska, complete removal of stover from a 4 year NT system reduced corn grain and biomass yields by about 23% (Wilhelm et al., 1986). Grain yield is often higher from residue mulched soils than from unmulched soils due to increased soil water content and favorable soil temperature in the growing season. Rates of crop residue mulch can explain as much as 95% of the variability in grain and biomass yield (Wilhelm et al., 1986; Blanco-Canqui and Lal, 2007a). Corn stover removal reduced corn yield by 1 Mg ha⁻¹ during 3 years of a 12 year NT continual corn study on a silt loam in Minnesota (Linden et al., 2000). Residue removal impacts on corn production are site-specific and depend on soil, topography, duration of stover management, tillage, and climate. Crop production in sloping, erosion-prone, and well drained soils can be more adversely affected by residue removal than in flat and clayey soils.

25.8.2 Positive Aspects of Crop Residue Removal

In some soils or ecosystems, it may be feasible to remove a portion of the crop residue for alternative uses in the short term without increasing risks of erosion by water and wind, reducing the soil OM pools, or reducing crop production. Indeed, removal of some of the total residue produced may be beneficial to improve seed germination, facilitate planting, increase N mineralization, and reduce pest infestations. Dam et al. (2005) observed that corn emergence in mulched plots was reduced by as much as 30% relative to unmulched plots. In a similar study, Blanco-Canqui et al. (2006) observed that corn stover removal from long-term NT soils enhanced seed germination on three soils in Ohio. Without stover removal, emergence was delayed by up to 3 days as compared with that on soils where all stover was removed. These studies showed, however, that the delayed emergence did not reduce crop yields. Plants in plots with low amount of residue cover often grow taller during the first few weeks, but the height differences often diminish rapidly with time.

Excessively wet and cold soils during the germination period, proliferation of weeds and pests, and nutrient immobilization under mulched soils may lower crop yields. On two silt loams in southwestern Wisconsin, corn yield decreased when stover cover was doubled (Swan et al., 1994). On a silty clay loam in Iowa, corn yield decreased during the last 4 years of a 13 year continual corn system with the addition of 2, 4, 8, and 16 Mg ha⁻¹ of stover mulch (Morachan et al., 1972).

25.8.3 Threshold Levels of Residue Removal

The magnitude of residue removal impacts on soils and crop production is site specific and information on maximum permissible rates of residue removal is limited. The positive and negative impacts of crop residue removal must, therefore, be characterized for different scenarios of tillage and cropping systems, soil characteristics, and climatic zones. Some computer-simulation model estimates in the United States, mainly for the Corn Belt region, show that 20%–50% of the residue produced

may be available for removal (Graham et al., 2007). These estimates, however, are mainly based on the residue requirements to control erosion. Permissible levels of residue removal must account for the residue requirements not only to control soil erosion, but also to maintain soil OM and nutrient pools, sustain corn yields, and maintain or enhance soil quality. Depending on the soil and climate, between 5.3 and 12.5 Mg ha⁻¹ of crop residue is needed to maintain soil organic C levels (Johnson et al., 2006; Varvel and Wilhelm, 2008). This amount exceeds that needed for controlling erosion (Wilhelm et al., 2007). Thus, the amount that can be harvested may be limited by the amount needed to maintain soil organic C pools.

The amount of stover that can be harvested for biofuel production must be established for different soils and ecoregions based on the multiple roles of residue. Process-based models are valuable tools for predicting the impacts of different scenarios of crop residue management across regional and national scales on the potential for erosion by water and wind. These models allow the scaling up of information on residue management to larger geographic areas. Use of current models combined with advanced tools such as remote sensing and GIS is a promising approach to enhance our understanding of residue removal impacts on soil and water resources (Green et al., 2003).

25.9 Soil Fertility and Nutrition

25.9.1 Nitrogen

All soil biological processes are greatly affected by the organic and inorganic portions of the N cycle. The N cycle is inextricably linked to the C cycle. The presence of mineral N in soil for plant uptake depends on what is happening within the C cycle. Because N is the most plant-growth-limiting nutrient and because it has been widely demonstrated that conversion to NT and other reduced tillage systems alters the C cycle, it is important to understand the specific effects of tillage systems on N availability to plants. As a result, soil testing and plant analyses are highly important components of effective nutrient management for successful crop production under CS conditions (Schlegel and Grant, 2006).

25.9.1.1 Immobilization of Fertilizer N

All CS and CT systems tend to immobilize N, but CS systems do not immobilize more N than CT systems; they only keep the N immobilized longer. Net N mineralization is eventually equal in all systems, but the timing of N release is delayed when residue is either slowly incorporated into the soil or left on the soil surface. Rice and Smith (1984) reported that within the first 35 days after application, N immobilization was 19% and 11% with NT and CT, respectively. Use of subsurface N-fertilization techniques may minimize immobilization in NT systems. Separating N and crop residue by placing fertilizer in soil below the residue was considered more important under CS than under CT systems (Schlegel and Grant, 2006). Because of immobilization differences, crop yields could be affected. Kelley and Sweeney (2007) showed that

wheat grain yields averaged 3.68, 3.40, and 3.19 Mg ha⁻¹ with subsurface knife, surface band, and surface broadcast applications, respectively, of N and P fertilizer in Kansas on Parsons silt loam (Mollic Albaqualf). Subsurface band application of N at greater rates was considered especially important when wheat followed grain sorghum in a rotation. Because of reduced immobilization, band applications of N fertilizer were more effective for production of durum wheat (*Triticum* spp.) (Grant et al., 2001) and canola (*Brassica* spp.) (Grant et al., 2002) in Canada. In Kansas, winter wheat yields were 8% greater with springtime point-injected than with broadcast N fertilizer application (Schlegel et al., 2003).

According to Schomberg et al. (1994), surface and buried residue both immobilized N, but net immobilization was longer than 1 year for surface residue and about 0.33 year for buried residue. Residue type, either grain sorghum or wheat, made little difference in terms of decomposition rate. Smith and Sharpley (1990, 1993) studied effects of residue type and placement on N immobilization and mineralization. Surface residue caused temporary N immobilization and the C:N ratio of the materials governed the duration of immobilization. Alfalfa (*Medicago sativa* L.) residue had the maximum mineralization followed by peanut (*Arachis* spp.), soybean, oat, sorghum, wheat, and corn in decreasing order. Although surface-placed residue had less N mineralized than buried residue, the difference between placements was minor compared with differences among residue types.

Soil OM contents are often very low under dryland conditions. In New Mexico, NT soils had less inorganic N and more organic C and N than a stubble mulch tillage soil after 5 years (Christensen et al., 1994). Unfertilized grain sorghum was very N deficient with the NT compared with the stubble mulch treatment. Soil organic C increased with time with NT and stubble mulch systems, but a point was not reached in the 5 year study where N mineralization with NT equaled that with stubble mulch tillage.

Immobilization delays N availability to plants, but the impact of N fertilizer management appears not to be as significant as once thought. Crop yields where no N is applied can be lower with NT than for other tillage systems due to immobilization with NT (Bundy et al., 1992). Nitrogen immobilization, however, may be affected by residue amounts on the soil surface. In Nebraska, increased residue levels resulted in greater grain yields in a tillage experiment and the additional residue increased stover production and N uptake by subsequent crops (Maskina et al., 1993). Nitrogen immobilization seemed not to be a factor. Tillage per se, that is, NT versus disked, did not affect grain yields. Vigil and Kissel (1991) developed equations to predict net N mineralization for a season based on N content and/or N + lignin/N ratio of the residue and concluded that net N mineralization would not occur if the C:N ratio of the residue was above 40.

25.9.1.2 Soil N and C Mineralization with Time with No-Tillage

Converting crop production to reduced tillage and NT systems affects the formation, size distribution, and strength of

soil aggregates. Changes in aggregate properties alter the rates at which both physical and biological processes proceed. When soils are not tilled, macroaggregates that form from natural processes tend to remain longer and have an opportunity to become strengthened. The more stable the soil aggregates, the greater the organic C stabilization in soil.

Soil organic C mineralization is a function of the interactive physical, chemical, and physicochemical processes that occur inside soil aggregates. Soil organic C is physically protected inside macro- and microaggregates through entrapment, and chemically through adsorption and recalcitrance (Blanco-Canqui and Lal, 2004). The confinement of C inside of aggregates prevents OM from rapid mineralization by microbial processes while enhancing long-term C sequestration. There is a mutual interrelationship between soil C and aggregates. The protected C pool enhances macro- and microaggregate formation and stabilization, while the microaggregates, in turn, protect the organic C from rapid mineralization.

The soil organic C residence times (mineralization rates) range from a few minutes to hundreds of years. Particulate OM or relatively labile OM can be mineralized in 5 or 10 years, while stable C can be mineralized in 500 or 1000 years (Blanco-Canqui and Lal, 2004). The residence times of C in soil aggregates is influenced by the type of organic binding agents, type of soil, size of aggregates, tillage, and climate. Mineralization of C normally increases with increases in aggregate size because of the differences in physical and chemical protection (Jastrow et al., 1996). In some cases, the C inside microaggregates can be protected physically, but be highly susceptible to rapid mineralization. The mechanisms of C mineralization or residence times inside aggregates are complex.

Macroaggregate formation often is greater in NT than in CT soils. These large aggregates with NT store more C because they are made up of a large number of C-enriched microaggregates. Beare et al. (1994a, 1994b) found that macroaggregates from NT soil protected soil OM from decomposition. In their study, 19% of the total mineralizable C and N in NT soils came from these larger aggregates, while only 10% and 5% of the C and N, respectively, came from them in CT soils. This aggregate-soil OM association under NT conditions may explain why conversion to NT results in a need for higher N fertilizer rates at the outset (Bradford and Peterson, 1999). Adjustments in N application rates during early years of adoption of NT were considered important also by Schlegel and Grant (2006). Apparently, a new steady state is reached and the immobilization capacity due to macroaggregate formation is fulfilled. In fact, Follett and Schimel (1989) inferred from data collected from a 15-year NT experiment that less tillage helped conserve mineral N. In other words, the greater, but temporary, immobilization of N under NT conditions reduced the opportunity for both leaching and denitrification losses of mineral N.

How long does the net immobilization period of NT last before mineralization processes equilibrate? Rice et al. (1984) observed that after 10 years, N mineralization with NT was equal to that with CT. The authors suggested that the net immobilization phase is transitory when NT is adopted. For a wheat-fallow system in western Nebraska, Lamb et al. (1985) reported that for the first 5–7 years after adoption of reduced tillage and/or NT, less NO₃–N accumulated during the fallow period than in plowed soils. Approximately 7 years after adoption, NT and stubble mulch tillage soils had NO₃–N accumulations during fallow equal to those in plowed soils and continued to have equal contents in subsequent years.

25.9.1.3 Fertilizer N Conservation and Efficiency

Perhaps of more concern than immobilization of N fertilizer is the potential loss of N from urea fertilizers applied directly to a residue-covered NT soil. In Missouri, substantial N losses occurred from urea-based N fertilizers under NT conditions when the fertilizer was not injected into the soil (Stecker et al., 1993a, 1993b). When N was injected below the residue, time and source of application had no effect on corn yield. In Wisconsin, ammonia losses reduced the effectiveness of urea-containing fertilizers, but such loss did not fully explain the observed N source differences. The N source effects were similar with all residue levels, which suggested that applying extra N can overcome yield reductions with high residue levels (Andraski and Bundy, 2008).

Under drier climatic condition, the effect of placing N below the residue depends on the season when crops are grown. For fall-planted wheat, hot and dry weather conditions at planting time in fall apparently stimulate N losses from urea compounds that are broadcast over the residue. In contrast, cooler and wetter weather at corn planting time diminishes the loss mechanisms, thereby causing minimal N losses (Kolberg et al., 1996).

Cold springtime soil temperatures are the rule in northern regions such as, for example, the U.S. northern Great Plains and, therefore, influence crop responses to N fertilizer. Spring wheat in a wheat-fallow system in the northern Great Plains responded most to N fertilizer in years when springtime NO₃–N levels were lowest, apparently because of greater N immobilization due to lower soil temperatures with CS systems (Halvorson et al., 2000). The NT and minimum tillage systems are considered suitable for spring wheat production in the northern Great Plains, but yields are slightly reduced when compared with CT systems in some years.

25.9.1.4 Crop Responses to Starter Fertilizer

Cool soil temperatures under NT conditions often slow early growth of spring-planted crops and, therefore, may affect their yield. To improve early growth and crop yields under such conditions, starter fertilizers are sometimes applied, but there appears to be no clear evidence indicating where the use of starter fertilizer is effective for improving crop growth and yields. Studies under varying conditions at different locations showed various responses to the use of starter fertilizers.

Wortmann et al. (2006b) in southeastern Nebraska applied NP and NP + S starter fertilizers as in-furrow, over-the-row, and 5 cm deep and 5 cm to the side of the seed treatments for grain sorghum planted under NT conditions. The soil orders were Mollisols, Alfisols, and an Entisol. The use of starter fertilizer

increased early growth by 48% in some trials where soil P was low, but grain yield responses to starter fertilizer were not related to the soil P content. Including S did not affect yield. Fertilizer placement effects on yields varied, but the frequency and magnitude of NT sorghum responses to starter fertilizer were not adequate to be profitable at the southeastern Nebraska sites. In contrast, in a similar study in eastern Nebraska where soil orders were Eutrudepts, Ustorthents, and Mollisols, application of starter fertilizer increased early corn growth by 30% in irrigated trials and by 10% in some rainfed trials. The use of starter fertilizer increased grain yields by 0.86 Mg ha-1 with irrigation, but only slightly without irrigation. Yields were similar with the different placement treatments. The yield response to starter fertilizer was greatest and most profitable under irrigated conditions where soil P was low. The conversion of early growth response to starter fertilizer into a grain yield response appeared to depend on soil water availability and on the soil P level (Wortmann et al., 2006a).

Under precision agriculture conditions for NT corn in Iowa, application of liquid NPK starter fertilizer in the seed furrow and beside and below the seed was compared with a no starter fertilizer treatment. The use of starter fertilizer often increased early growth and increased yield in some fields having a low soil P value, but decreased yield in one field. With high P values, yield responses were $0.08-0.19\,\mathrm{Mg}$ ha⁻¹ with starter fertilizer applied in the furrow and $0.16-0.46\,\mathrm{Mg}$ ha⁻¹ when applied beside and below the seed. Across fields, the early growth response was linearly but poorly correlated with the yield response (2.4%). With NT, corn yield responses to starter fertilizer are apt to be greatest when the soil P value is below optimum or when preplant or side-dress N rates are deficient (Bermudez and Mallarino, 2002).

To evaluate corn responses to starter fertilizer and tillage treatments, Bermudez and Mallarino (2004) in Iowa had starter or no starter fertilizer treatments in addition to farmers' normal broadcast application rates of NPK. Tillage treatments were spring disking, strip tillage on previously managed NT fields, and non-tilled NT fields. The use of starter fertilizer increased corn grain yield in some fields (up to 0.52 Mg ha⁻¹) and tillage increased yield up to 0.50 Mg ha⁻¹ in some fields, but the overall average yield increases were small. Dry matter and nutrient uptake responses to both treatments did not result in large or consistent yield responses. Soil test results or soil series could not always be used to identify fields where an application of starter fertilizer would increase corn yield.

In Kansas, Niehues et al. (2004) applied starter fertilizer containing N, P, K, and S (with subsurface placement) as direct seed contact, dribble over-the-row, and subsurface band 5 cm below and 5 cm to the side of the seed row treatments for NT corn production. For all treatments, N was balanced at 0.17 Mg ha⁻¹ by applying ammonium nitrate (AN) at planting, even for the nonstarter check treatment. Regardless of placement, the use of starter fertilizer often increased early dry matter production and significantly increased corn grain yields. Including S sometimes increased early dry matter production, grain yield, and nutrient uptake. For this study, the use of a starter fertilizer was an

effective and efficient way to stimulate early growth and improve grain yields of NT corn grown continually in Kansas.

The aforementioned studies showed that there is no universal response to the use of starter fertilizer for improving crop growth and yields. The different studies under varying conditions at different locations clearly showed different responses to the use of starter fertilizers. Early growth often was greater where such fertilizer was applied and yields increased in some cases, but the yield increases were slight in most cases. Consequently, the question regarding whether starter fertilizer should be applied remains unanswered.

25.9.1.5 Crop Responses to Fertilizer (Nonstarter)

As for any other tillage method, crops grown under CS conditions respond to applied fertilizer. The degree of response depends on the inherent soil nutrient level. A response difference with CS, especially NT, relative to that with CT may occur due to the method of application. With CT, the fertilizer generally is placed into the soil before or when planting occurs. With NT, the fertilizer may be broadcast on the surface. Broadcast application, however, is satisfactory under NT conditions as indicated for a study with cotton in Tennessee (Howard et al., 2001). Relative to no N application, broadcast application of AN at 67 kg N ha-1 increased average lint yields from 0.74 to 1.28 Mg ha⁻¹ on Loring silt loam (Oxyaquic Fradiudalfs) and from 1.09 to 1.54 Mg ha-1 on Lexington silt loam (Utlic Hapludalfs). A rate of 101 kg N ha⁻¹ was needed to increase average yields on Memphis silt loam (Typic Hapludalfs) from 0.82 to 1.17 Mg ha⁻¹. Broadcasting AN was satisfactory for producing lint yields equal to or higher than those obtained by injecting urea-AN or splitting AN applications on the loess soils having different surface covers or residue.

25.9.2 Phosphorus and Potassium

Reduced and NT systems tend to keep soils cooler than clean tillage systems (see explanation in previous sections). For spring-planted crops in northern latitudes of the northern hemisphere, this results in slower plant root growth with reduced tillage systems. Because P is an immobile nutrient and uptake depends greatly on root interception, cold soils can create temporary P deficiencies. Starter fertilizers placed near the seed at planting may be beneficial in such cases. Failure to correct the temporary P deficiency stunts plant growth and delays development so that the crop may fail to mature before frost occurs in the fall. For a wheat-fallow system, placing P fertilizer with the seed was more beneficial under NT than for plowed and/or reduced tillage (stubble mulch) systems (Stecker et al., 1988). Apparently, cooler soil temperatures under high residue conditions in the spring were responsible for this difference.

In contrast to P, K is much more mobile in soils. Uptake of K and its effect on crops, however, may be influenced by placement as a fertilizer under NT conditions. In Iowa, P and K at various rates were broadcast, banded with the planter, or deep banded (at 15–20 cm depth) to determine their effect on early

growth, grain yield, and nutrient uptake by NT soybean. The study involved nine soil series on Argiudolls, Endoaqualfs, Endoaquolls, and Hapludolls. Yields increased with P fertilization when soil-test P was <9 and <12 mg kg⁻¹ at the 0–15 and 0–7.5 cm depths, respectively. Band placement of K resulted in slightly higher yield than broadcast placement. Responses to K were not related to soil-test K values or stratification in the soil. Placement of P and K had little effect on early soybean growth, but affected early P and K uptake. Banding with the planter was more effective than broadcast application for P uptake, but both depths of band placement were more effective than broadcast application for K uptake (Borges and Mallarino, 2000).

No clear-cut recommendation can be made regarding when and how to apply K fertilizer. Therefore, producers should rely on soil test results and associated recommendations for their particular soil, cropping system used, and crop to be grown. Xinhua and Vyn (2002a) in Indiana found that NT soybean responded to K applications on some soils, but there was no yield difference whether the K was banded or broadcast. In another study involving different row spacing for soybean, band placement was superior to broadcast application of K fertilizer (Xinhua and Vyn, 2003). The response was greatest when soybean was seeded over the K bands. Also in Indiana, Vyn and Janovicek (2001) found that NT or zone-tilled corn responded to starter K fertilizer applied at a high rate, even when no K fertilizer was applied the previous fall. Fall or spring application of K fertilizer for corn was equally beneficial for the subsequent soybean crop under continuous or intermittent NT conditions (Xinhua and Vyn, 2002b).

When soils are sampled to determine P fertilizer requirements, the test results may be influenced by the previous P application method. The P fertilizer application method under NT conditions may affect P distribution in soil for months or even for years because P is highly immobile in soils. To quantify the spatial distribution and temporal dynamics of band-applied P and to assess its availability to crops, Stecker et al. (2001) obtained soil samples in a grid pattern around bands where 10 and 20 kg ha⁻¹ of starter fertilizer P was applied about 6, 12, and 24 months previously. Soils were Mexico silty clay loam (Mollic Epiaqualf), Putman silty clay loam (Vertic Albaqualf), and Dockery silt loam (Aquic Udifluvent). The P concentrations decreased outward from the band center, were highest at either 6 or 12 months, and varied substantially along the direction of band application. The results indicated that including bands in soil tests would increase the risk of overestimating the amount of P that is available to crops.

Application of P and K fertilizers under continuous NT conditions may result in their stratification similar to that which occurs with band application. As a result, special sampling techniques may be needed to adequately determine the nutrient status of NT soils. For a study on three silt loams (Memphis, Lexington, and Loring) in Tennessee to which K had been broadcast at various rates for NT cotton production, Howard et al. (1999) determined P and K distribution with depth at inrow and between-row positions. Sampling depths were 0–8,

8–15, and 15–30 cm. The soil-test P level varied with soil, sampling position, and soil depth, but differences due to sampling positions (in-row or between-row) did not affect soil test ratings. Additional years under NT cotton production, however, could increase position influences and, therefore, affect P fertilizer recommendations. The soil-test K level was greater at the in-row position at the 0–8 cm depth of all soils. As a result, sampling only between rows could give a lower test value in some cases. The differences varied with fertilizer K rates and could increase with time of NT cotton production.

25.10 Surface Sealing, Crusting, and Seedling Emergence

Conservation tillage, particularly NT, reduces surface sealing and crusting compared with CT by maintaining permanent residue cover. Seal formation on a freshly cultivated soil exposed to the beating action of falling raindrops is due to two mechanisms, namely, the breakdown of soil aggregates by the impact force of raindrops and a physiochemical dispersion of soil clays. The initial water condition of aggregates at the beginning of a rainstorm affects their resistance to breakdown or dispersion (le Bissonnais, 1990). For initially dry aggregates, the breakdown is mainly due to slaking. The dry surface slakes rapidly under wetting and forms a seal of lower permeability. If the water content of the soil surface is high before rainfall, the degree of aggregate breakdown and surface sealing is low and results primarily from the mechanical impact of raindrops (Bradford and Huang, 1992). Wetting and drying of newly formed crusts (dry seals) normally act to weaken the crust and it may largely disappear as the soil surface granulates. Even though drying forms new aggregates, their size and stability are less than those of the original surface, and the final infiltration rates at the end of subsequent storms are lower than rates at the end of the first storm (Ben-Hur et al., 1985).

Soils crusts reduce seedling emergence, but their final effect on yield is crop dependent. For example, in the coarser-textured soils in the Lower Rio Grande Valley of Texas, cotton under CT conditions often must be replanted due to crusting following an intense rainstorm that prevents or greatly limits seedling emergence (Bradford and Peterson, 1999). The same is true for many soils in the southeast United States (Miller and Radcliffe, 1992).

The extent of soil crusting and its effect on seedling emergence are highly dependent on the tillage system used and the amount of residue cover. Maximum crusting usually occurs with mold-board plowing followed by disking several times. While surface sealing and crust formation are minimized in CS systems by maintaining high crop residue cover percentages, the high levels may have some negative effects, for example, reduced and uneven seedling emergence, particularly in regions with cooler and wetter climates. In regions where spring planting is delayed by snow melt and warming of the soil, seedling emergence is less with CS than with CT unless crop residue is partially removed from the row. Uneven crop emergence and reduced stand density

were reported in the northern Corn Belt in Wisconsin (Carter and Barnett, 1987), Iowa (Mock and Erbach, 1977), Minnesota (Ford and Hicks, 1992), and Illinois (Nafziger et al., 1991). By using injection knives to apply fertilizer and till the soil ahead of planting, Greiner (2008) reported that the tilled zone at planting time usually is warmer, the seeding zone is somewhat drier, and seedling emergence occurs sooner than where residue is not removed. Row-zone tillage in which narrow bands are tilled to satisfy the seedbed requirements allows most of the area between rows to be managed to improve infiltration and control runoff and erosion (Burwell et al., 1968).

25.11 Compaction

Soil compaction is defined as the volume change produced by momentary load application caused by rolling, tamping, or vibration. It is the process by which soil grains are rearranged into closer contact to decrease void space. Compaction removes air from the soil without significantly changing the amount of water in the soil. Compaction can result from external forces such as traffic by tractors, implements, and other farm machinery or from internal forces (sometimes termed consolidation) resulting from increased drying, overburden, or changes in the groundwater table. The usual effects of compaction are increased soil bulk density, shear strength, resistance to probe penetration, and decreased soil compressibility and permeability. Soil drying or desiccation not only results in increased soil bulk density, but also soil cracking and development of macropores if expanding lattice clays are present (Bradford and Peterson, 1999).

One of farmers' primary concerns in switching to NT systems is the problem of soil compaction. Bulk density and soil strength can be less for plowed than for NT soil (Mielke et al., 1986; Bruce et al., 1990; Hill, 1990; Cassel et al., 1995). Bulk densities in the surface 75 mm were higher in four Midwestern U.S. NT soils, no differences in two, and less in one (Mielke et al., 1986). At the 75-150 mm depth, bulk density was greater with NT for only two soils. Clay contents were similar, ranging from 23% to 36%, and time in NT ranged from 6 to 13 years. After 28 years, bulk density of Wooster silt loam (Typic Fragiudalf) at Wooster, Ohio, was lower for continual corn with NT than with other tillage (moldboard plow and chisel plow) and crop rotation treatments (Lal et al., 1994). For a regional study across Ohio, Indiana, and Pennsylvania, Blanco-Canqui and Lal (2007b) reported that NT farming had moderate impacts on soil compaction. They observed that cone index, a parameter of soil compaction, was greater with NT than with CT in 9 out of 13 soils, while bulk density was greater with NT only in 2 soils. These increases in soil compaction parameters with NT were, however, small and well below the threshold levels of excessive compaction.

In poorly structured soils with low OM, long-term NT can lead to higher soil strengths that may limit root growth and crop yields. In most soils, however, even though strength and bulk density under NT conditions are often greater than under CT conditions, crop yields are seldom reduced (Radcliffe et al., 1988). Detrimental effects of greater compaction are often negated by

more positive effects of increased water infiltration, reduced soil temperature, reduced soil water evaporation, and greater water storage. Also, roots under NT conditions grow into existing root channels, worm holes, or fractures between soil structural units. As a result, root growth may actually be greater under NT conditions (Merrill et al., 1996).

Although use of NT provides various benefits on soils subject to compaction as mentioned earlier, cotton yield reductions have jeopardized NT adoption in the Tennessee Valley region of northern Alabama. Subsoiling reduced the compaction index 12% and 15% compared with non-subsoiled CT and NT soils, respectively. Fall deep non-inversion tillage by either paratilling or in-row subsoiling with a narrow-shank subsoiler resulted in cotton yields 16% and 10% greater than with CT and NT, respectively, for which the soil was not loosened. Non-inversion in-row deep tillage in fall coupled with a rye cover crop that produces adequate residue to provide for erosion control and water conservation is a highly competitive and practical CS system for the region (Schwab et al., 2002).

In addition to soil compaction that may result from performing cultural operations for crop production, compaction may result from other traffic in fields such as spreading fertilizer or manure, pesticide applications, and harvesting operations (harvester and grain hauling). In many cases, the weight of such equipment plus their loads is greater than that of equipment used for cultural operations and, therefore, may lead to severe soil compaction. To some extent, the degree of compaction may be controlled by the tire pressure or type of tires on the equipment. For a study on Hublersburg silt loam (Typic Hapludult) in Pennsylvania, NT soil was not compacted or compacted annually with a truck having road tires (700 kPa inflation pressure) or flotation tires (250 kPa pressure) that provided a 10 Mg axle load. In-row tilling the compacted soil 40 cm deep resulted in corn yields similar to those with NT without compaction in 3 years and greater yields in 1 year. The results showed little need for in-row tillage to manage compaction under long-term NT conditions when axle loads do not exceed 10 Mg and when using flotation tires that have inflation pressures <250 kPa (Sidhu and Duiker, 2006). Also, practicing controlled-traffic farming minimizes the potential for the development of severe compaction problems (Tullberg et al., 2007). Clearly, careful management regarding equipment used for cultural operations and other equipment traversing fields is important for minimizing soil compaction.

The degree of soil compaction is gradually reduced with time under NT conditions. Macroporosity and earthworm channels generally are greater in NT soils (Drees et al., 1994). In the subtropical, semiarid regions of Texas, earthworms are abundant in NT soils, but absent in CT soils (Bradford and Peterson, 1999). Even in colder semiarid regions such as North Dakota, changing to an NT system greatly enhances earthworm populations (Deibert and Utter, 1994).

NT soils develop an intrinsic ability to resist excessive soil compaction with time, depending on OM input, soil type, management, and climate. Accumulation of soil organic C is one of the main causes for the reduced susceptibility of NT soils to compaction in the long term. Soil OM confers elasticity and resilience to soil because of its low density and high specific surface area. Accumulation of organic C near the soil surface in combination with residue mulch cover can reduce compaction and compression. In turn, CT accelerates decomposition of soil OM, reducing the soil's ability to resist compaction and compression. Thomas et al. (1996) and Assis and Lancas (2003) reported that soil compactibility as determined by the Proctor test was much lower with NT than with CT in temperate and tropical soils, due to the greater organic C accumulation in NT soils. Soil compactibility is negatively correlated with organic C content.

The potential for plow pans or other mechanically compacted layers to develop is sharply reduced when using smaller tractors, performing less tillage, and making fewer trips across the field, which occurs for crop production under CS, especially NT, conditions. Furthermore, compaction of soil surface layers by raindrop forces or surface sealing is less under CS due to protection of surface soil layers by greater residue cover. Consolidation of surface layers due to desiccation is reduced with greater residue cover under CS because of less soil water evaporation.

The degree of reconsolidation and compaction that occurs when plowing is eliminated depends on the crop rotation, amount of surface residue, control of wheel-traffic, climatic factors (rainfall and temperature), and soil variables. Soil variables include soil texture and structure, clay mineralogy, OM content, and others. Compaction due to tractor and machinery traffic and consolidation from desiccation are more of a problem in coarser-textured soils with massive structure and low OM levels, especially with monocultures of low residue crops such as cotton and soybeans, than in fine-textured soils. For example, reduced yields due to soil compaction have been reported for the highly weathered soils of the southeastern United States (Touchton and Johnson, 1982), whereas compaction is less of a problem for deep loessial soils in Illinois and Indiana (Bradford and Peterson, 1999).

Soil compaction problems must be corrected by mechanical means before starting an NT system (Radcliffe et al., 1988), or crop yields on some soils may be reduced for several years until biological forces loosen the soil. To reduce soil reconsolidation or if traffic compaction occurs, a paratill or similar tool that loosens the soil from beneath, leaves the surface relatively smooth, and maintains residue of the previous crop on the surface can be used (Unger, 1993). Soil compaction in the upper horizons can also be reduced with strip-tillage in the row (Radcliffe et al., 1989; Raper et al., 1994) or while applying fertilizer with fertilizer knives.

By controlling traffic patterns, compaction is generally confined to the wheel track areas (Larney and Kladivko, 1989; Liebig et al., 1993; Sweeney et al., 2006). About 70%–90% of traffic compaction occurs during the first pass of a tractor or machinery. By not controlling traffic patterns, therefore, compaction in the entire field is possible. With time, soil compaction is gradually alleviated by biological means when using a CS system. After 3 years on Willacy fine sandy loam (Udic Argiustolls) in south Texas, soil structure was improved, yields were equal to those

with CT, and the compaction problem was gradually reduced by using NT (Bradford and Peterson, 1999). Wheel track compaction can also be reduced by performing chisel tillage (Sweeney et al., 2006).

25.12 Cropping Systems

Production of any crop involves some type of cropping system. The system may involve growing the same crop each year (continual cropping), the same crop grown alternately with fallow periods, or two or more different crops grown in a rotation. Some results were given and some comments were made regarding cropping systems in previous sections. In this section, we stress, among other factors, including the use of CS, the importance of cropping systems for storing and making better use of soil water, crop production by using shorter fallow periods, recognizing concern about herbicide carryover to succeeding crops in a sequence, identifying possible substitute crops if one crop is destroyed (hail damage, delayed planting, etc.), and cropping system effects on soil properties.

In the 1930s, the combination of a major drought and clean tillage used for crops at that time resulted in catastrophic erosion by wind in the semiarid U.S. central and southern Great Plains. Stubble mulch tillage was developed during that period to help control erosion and it also improved soil water conservation (Greb, 1979). When stubble mulch tillage is used repeatedly to control weeds, it can result in less than 30% surface residue cover when the next crop is planted. This is especially the case for a wheat-fallow cropping system that results in one crop in 2 years with a fallow period of about 15 months between crops. The low amount of residue remaining increases the potential for erosion and has generally resulted in low water storage efficiencies, often <25% (Haas et al., 1974; Johnson et al., 1974; Farahani et al., 1998). As a result, fallowing that has long been a controversial practice because of the low water storage efficiencies associated with it has, therefore, been replaced by more IC systems in some cases.

With the development of herbicides in the 1940s and continued development of even more effective herbicides through the years, reduced tillage and even NT crop production became possible. This resulted in further improvements in soil water conservation because of less water use by weeds, improved water infiltration, and decreased soil water evaporation. As a result, the controversial practice of using long fallow periods has been replaced by more IC systems in some cases.

With adequate surface residue, which is possible by using CS, especially NT, water conservation is improved and conditions become favorable for reducing the length of fallow periods and increasing cropping intensity. For the southern Great Plains, a winter wheat-grain sorghum-fallow (WSF) system that results in two crops in 3 years is well adapted. This system involves fallow periods of about 11 months between the crops and increases annualized grain yields relative to those with a wheat-fallow system (Baumhardt and Anderson, 2006). For a WSF study at Bushland, Texas, wheat straw was placed on Pullman clay loam

at rates ranging from 0 to 12 Mg ha⁻¹ at the time of wheat harvest. Plots were not tilled during the ensuing fallow period. When grain sorghum was planted about 11 months later, fallow period precipitation storage as soil water averaged 23% and 46% with the 0 and 12 Mg ha⁻¹ residue treatments, respectively. Dryland sorghum grain yields averaged 1.78 and 3.99 Mg ha⁻¹ with the respective treatments (Unger, 1978).

The use of some type of CS has been shown to be suitable for various cropping systems in the central and northern Great Plains. A winter wheat-corn (or grain sorghum)-millet-fallow cropping system avoids long fallow periods and results in three crops in 4 years in the central Great Plains (Wood et al., 1991). Cropping systems that reduce fallow length in the northern Great Plains include spring wheat-winter wheat-fallow (two crops in 3 years); safflower (*Carthamus tinctorius* L.)-barley-winter wheat; spring wheat-corn-peas; spring wheat-winter wheat-sunflower; and spring wheat in rotation with soybean, peas, safflower, sunflower, buckwheat (*Fagopyrum esculentum* Moench), or canola (Black, 1986; Black and Tanaka, 1996; Unger and Vigil, 1998).

By increasing cropping frequency, the proportion of fallow that occurs in fall, winter, and spring months is increased, thereby resulting in the highest precipitation storage efficiency. Also, it greatly decreases or avoids the fallow extending in the second summer when no additional precipitation is stored as soil water (Peterson and Westfall, 2004).

The foregoing examples stressed the importance of improving soil water storage in an effort to increase cropping intensity by reducing the length of fallow in the cropping system. Even with fallow, however, water availability for dryland crop production is strongly influenced by precipitation amount and time of occurrence, which are highly unpredictable. Rigid cropping systems rely on growing certain crops at predetermined times. Occasionally, however, substantial amounts of precipitation occur late in the growing season or soon after harvesting a crop, thereby possibly negating the opportunity for storing much additional water during the ensuing fallow period. When such condition develops, opportunity cropping can be used to grow an adaptable crop to use the water that has become available and to eliminate or shorten the originally planned fallow period. In the southern Great Plains, for example, short-season grain sorghum can be grown after harvesting winter wheat and winter wheat can be grown after harvesting grain sorghum. Other crops evaluated for opportunity cropping in a study at Bushland, Texas, were forage sorghum (Sorghum spp.), pearl millet, oat, triticale (X Triticosecale Wittmack), kenaf (Hibiscus cannabinus L.), pinto bean (Phaseolus vulgaris L.), and fall and spring canola (Unger, 2001). Crops suitable for opportunity cropping were winter wheat, grain sorghum, triticale, forage sorghum, pearl millet, and oat. Opportunity cropping is a more intensive system than fixed cropping systems. As a result, precipitation use efficiency is greater than with systems involving long fallow periods. For a 5 year study in the central Great Plains, economic precipitation use efficiency (i.e., value of crops produced) was 45% greater with opportunity cropping than for set rotations that included fallow (Nielsen et al., 2006).

The producer's goal for cropping systems generally is maximum crop yields, but the economics of production are important also with tillage system often influencing the economic returns. For a dryland study in North Dakota, DeVuyst and Halvorson (2004) evaluated the economics of SW-F and spring wheat-winter wheat-sunflower IC systems under CT, minimum tillage, and NT conditions and various N levels. For the IC system, minimum tillage resulted in greater profits than CT and NT under the same N treatments, but profits were more variable with minimum tillage. The highest N rates resulted in the greatest profits. The IC system with minimum tillage or NT was more profitable than the best SW-F system with CT at that location. Analyses revealed that the SW-F system and the IC system with CT were economically inefficient as compared with the IC system using minimum tillage or NT.

Under more humid conditions than in the Great Plains, crops are grown without fallow, but crop rotations are still widely used. For a corn-soybean rotation study in Minnesota, NT after soybean reduced corn yields in 2 of 4 years compared with full-width fall chisel tillage and spring field cultivation. Also, full-width tillage for soybean in rotation with zone tillage or fall strip tillage for corn resulted in greater corn yields and economic returns than annual full-width tillage. Soybean yields were greater with rotational tillage, but the difference among tillage systems was not large enough to provide an advantage to full-width tillage. Considering both crops, rotational tillage provided for greater yields, but not greater economic returns (Vetsch et al., 2007).

Simplified crop rotations lead to deterioration of soil physical, chemical, and biological attributes and adversely impact crop production. Diverse and consequently more IC systems in combination with reduced tillage and NT that improve soil attributes and sequester C are potential alternatives to crop-fallow systems (Pikul et al., 2006; Benjamin et al., 2007). Impacts of cropping systems on soil properties differ from those of tillage treatments. Cropping system impacts on soil conditions and C sequestration are often detectable for longer periods than with tillage treatment impacts (Benjamin et al., 2007).

Cropping systems alter soil functions because of differences in the amount of above- and below-ground biomass input and rooting patterns. Differential surface cover among cropping systems influences changes in surface soil processes (e.g., surface crusting) and properties (e.g., water infiltration, aggregate stability). High-biomass producing crops in combination with reduced tillage and NT systems improve soil surface conditions. Plant roots through deep extension and proliferation can alter pore-size distribution by creating fine and coarse root channels within the soil profile (Benjamin et al., 2007).

Impacts of cropping systems on soil properties are not always consistent, depending on soil, length of management, and climate. After 15 years of management, Benjamin et al. (2007) observed no differences in soil bulk density, pore-size distribution, water retention capacity, and saturated hydraulic conductivity due to using wheat-fallow, wheat-corn-fallow, wheat-corn-sunflower-fallow, and wheat-corn-millet rotations under NT on a silt loam

in eastern Colorado. Also in eastern Colorado, Shaver et al. (2003) found that the use of NT for 12 years in IC systems including continual cropping, wheat-corn-fallow, and wheat-sorghum-fallow reduced soil bulk density and increased soil porosity, but had no affect on sorptivity when compared with a wheat-fallow system. On a regional study across eight locations in the Great Plains, Pikul et al. (2006) observed that cropping system effects on soil structural properties were highly soil dependent.

25.13 Cover Crops

Cover crops may play an important role within a CS system by protecting the soil against erosion by wind and water, increasing soil OM, improving soil structure and other soil physical properties, altering soil temperature and soil water content, and increasing fertility by recycling nutrients and providing biologically fixed nitrogen (in the case of leguminous cover crops). Cover crops also can improve weed control through competition (Vasilakoglou et al., 2006) or allelopathic effects, and may improve environmental quality through the protection of surface and ground waters. Efficient use of cover crops in management systems, however, depends on the purpose of the cover crop and on factors such as prevailing temperatures, length of growing season, and rainfall amount and distribution (Bradford and Peterson, 1999).

Cover crops generally are more adaptable to farming systems in the southeastern United States because of greater rainfall than in drier climatic regions (Bradford and Peterson, 1999). The goal for a study by Schomberg et al. (2006) in Georgia was to achieve a better understanding of cover crop and tillage system interactions that can lead to greater productivity and economic returns for cotton production. That study on Bonifay fine sand (Grossarenic Plinthic Paleudults) involved seven different cover crops and strip tillage or NT. Cover crop biomass was greatest with rye and hairy vetch (Vicia villosa Roth) and the most N (80 kg ha⁻¹) resulted from Austrian winter peas (*Pisum sativum* ssp. arvense). Other cover crops were balansa clover (Trifolium michelianum ssp. balansae), crimson clover (Trifolium incarnatum L.), oil seed radish (Raphanus spp.), and black oat (Avena strigosa Schreb.). Strip tillage increased yields and annual returns over those with NT, probably because of improved availability of water. Strip tillage with black oat as a cover crop was the best combination for maximizing profit under the conditions studied. It increased profits for cotton by \$50-\$75 ha⁻¹ over those for systems where rye was the cover crop.

Although cover crops seemingly are more adaptable to the more humid regions, they may have advantages in other regions also. In Missouri, maximum dry matter yield in spring resulted from a hairy vetch cover crop that provided 44 and 57 kg N ha⁻¹ in corn and grain sorghum experiments, respectively. Greatest corn and grain sorghum yields, however, were obtained with either hairy vetch or Austrian winter pea cover crops (Reinbott et al., 2004). In California, the presence of cover crops increased the steady infiltration rate by 37%–41% and cumulative infiltration by 20%–101% as compared with conditions without cover

crops (Folorunso et al., 1992). Timely killing of cover crops is essential to achieve maximum benefits from their use (Wagner-Riddle et al., 1994; Duiker and Curran, 2005).

In northern climates, cover crops often are not used because they generally result in soils being cooler in the spring, reduce the water supply for subsequent crops, and tend to shorten the growing season for subsequent crops. In U.S. semiarid regions, greater water stress and, therefore, potentially lower yields of subsequent crops are major constraints to using cover crops (Unger and Vigil, 1998; Baumhardt and Lascano, 1999). Also, farmers are reluctant to use cover crops because of the additional cost for their establishment and termination.

Intense management is required to achieve success with cover crops (Unger and Vigil, 1998). Time to kill the cover crop in the spring is critical to yield of the ensuing crop due to factors such as soil drying and warming, insect and weed pressure, and planter performance. Late April or early May kill dates consistently resulted in greater corn yield than earlier kill dates in Maryland (Clark et al., 1997). Soil water conservation during summer resulting from the presence of cover crop residue was more important than spring water depletion by growing cover crops in determining final corn yield.

25.14 Comparison of Conservation Tillage with Conservation Agriculture

Conservation agriculture (CA) "is a concept for resourcesaving agricultural crop production that strives to achieve acceptable profits together with high and sustained production levels while concurrently conserving the environment" (FAO, 2008). Based on several reports, CA is a system of integrated soil, water, and agricultural resources management. The main objective is economical, ecological, and socially sustainable agricultural production while the soil is regenerated or soil degradation is reversed. The system involves maintaining a permanent soil cover, practicing minimum soil disturbance, and using crop rotations. Benefits include fuel, implement maintenance and replacement, labor (time) savings, greater and more stable crop yields, and a lower requirement for heavy work. Other benefits are crop diversification; food security and diet improvements; improved water availability, amount, and quality; improved soil fertility and regeneration; less erosion; improved air quality; and greater agricultural biodiversity, namely, more diverse crop rotations, enhanced soil biodiversity, and less pressure on marginal lands, forests, and natural reserves (Hobbs, 2006; Unger, 2006). In essence, many characteristics of CA are also embodied in CS, especially the NT type of CS.

The key principles of CA are minimum mechanical soil disturbance, permanent soil surface cover with organic materials, and use of crop rotations involving more than two crop species (FAO, 2008). In its maximum condition, NT could meet the principles of CA, but, according to its definition, requirements

for NT do not meet the requirements for CA. For example, soil disturbance with a subsoiler is possible with NT whereas no such disturbance is appropriate with CA. Also, complete cover of the surface is required for CA, but not for NT. It is, however, important to recognize that a high level of residue cover is also essential for NT if soil and water conservation and soil C sequestration are priorities. Finally, CA requires use of crop rotations with more than two crop species. In contrast, NT can be practiced with one crop grown continually. Both systems, however, can provide for excellent control of erosion by wind and water and improve water conservation, crop production, and environmental conditions as well as many of the benefits mentioned earlier. As a result, either system may have its place in a given locale.

Although CA is a highly beneficial system, as previously mentioned, there are problems associated with its use (FAO, 2006, 2008). First, there may be financial constraints for producers to adopt CA because of the need to purchase new equipment and the initially lower crop yields with the system (CA is based on establishing an organic layer and producing its own fertilizer, which may take time and thereby cause yields to be lower than those previously obtained). Second, there seemingly is not enough pressure to adopt CA in some parts of the world because the need for an intensive conservation system as CA is not fully recognized and, therefore, it is not adopted. Finally, with the initial reduction in crop yields when changing to CA, it may be difficult to produce adequate food for the ever-increasing world population.

25.15 Soil by Climate Interactions

Surface residue has major benefits for agriculture, among the foremost being improved soil and water conservation. The level of benefits is controlled by the particular soil and climatic conditions at a given location. Surface residue also may have effects on agroecosystems that are detrimental to plant growth and require management adjustments to ameliorate. For example, soil temperatures are reduced by residue cover, which can negatively affect spring-planted crops in northern latitudes.

The interactive effects of surface residue with soil and climatic factors determine whether the residue effects are positive, neutral, or even negative. Primary issues are problems with cold soil temperatures, excessively wet soil conditions, and high runoff situations; interactions affecting crop rotation choices and weed control; and using surface residue management in conjunction with other conservation measures.

25.15.1 Problems Related to Cold Soils and Excessive Soil Water

In cold and humid climates, lower crop yields obtained with NT are often attributed to lower soil temperatures and excessive soil water contents during the early growth of spring crops, especially when crop residue is not removed from the row (Fausey and Lal, 1989). McCalla and Duley (1946) showed that corn residue mulches decreased soil temperatures in midsummer (July–August) at Lincoln, NE, by 3°C–7°C as mulch rates varied from

5 to 20 Mg ha⁻¹. This exemplifies an ameliorating effect of residue on a negative process, namely, summertime evaporation. In contrast, Al-Darby and Lowery (1987) showed that a cover of 55%-87% under NT conditions lowered soil temperatures by as much as 4°C compared with those with CT under spring conditions in Wisconsin. Corn seedling emergence (100%) was delayed by 2-8 days with NT compared with those with CT systems. Although emergence was delayed and plant growth was slower early in the season, corn grain yield differences were not significant. Al-Darby and Lowery (1987) concluded that the additional water saved with NT compensated for the early delays in plant growth. Also in Wisconsin, Carter and Barnett (1987) reported that for continual corn with NT, soil temperatures were cooler, emergence percentage and stand establishment were lower, and phenological development was delayed compared with corn produced using a moldboard plow system. Soil temperature at the 2-cm depth in barley plots in the semiarid region of southern Alberta, Canada, averaged 13.9°C with NT and 14.7°C with CT in spring (May), but these differences disappeared later in the growing season and grain yield was not affected (Carefoot et al., 1990).

Residue cover does delay plant development. For example, corn grown in residue-covered plots in Michigan required 3.5 more days to reach the VT (designated as the transitional stage between the vegetative and reproductive stages, namely, tasseling) stage in 1987 and 8 more days in 1988 (Fortin and Pierce, 1990). Producers must be prepared to deal with delayed growth of spring crops in reduced and NT systems because of low soil temperatures. Delayed emergence, for example, may reduce crop competition with weeds and allow them to flourish; such weeds use water and nutrients (e.g., N) and could ultimately decrease crop yields. Therefore, proper attention to weed control, planting dates, cultivar selection, and possibly starter fertilizer application is needed when it is known that cold stress will occur. In general, the need for intense management increases whenever additional stresses are imposed.

Soil properties that affect water infiltration, permeability, and drainage must always be properly assessed when making residue management decisions. Factors that cause soils to remain wetter longer generally cause them to be colder. Again, this is only a problem with spring-planted crops such as spring cereals, soybean, corn, and grain sorghum at northern latitudes. The latter two species are much more sensitive than small grains under these conditions. Research in the Corn Belt of the United States, showed that use of NT on poorly drained soils results in lower yields than use of CT. Long-term research has shown, however, that continued use of NT and disease-resistant cultivars has overcome the negative response. Also, grain yields after 18 years of NT are now equal to or greater than those with CT. Grain yields on well-drained soil increased with time under the NT system (Dick et al., 1991). Producers with poorly drained soils should expect lower productivity in the initial years after switching to high residue systems. It even may be best to avoid complete NT in these situations. Better choices may be ridging and bedding that reduce adverse effects of high residue systems on poorly drained soils.

Soil texture, slope, and drainage classification are the key factors in making decisions about tillage system choice (Peterson, 1994). Poorly drained soils are not easily adapted to high residue systems. Coarse-textured soils, even when poorly drained, are less of a problem than fine-textured soils in the same drainage category. Well drained soils are good candidates for NT or reduced tillage if they have a silt loam or coarser texture. Silty clay loam and silty clay soils may present problems for planting equipment if they are wet and, therefore, would be best managed with a more disturbed-soil system; perhaps ridge tillage. All steeply sloping soils regardless of textural class are best managed with reduced or NT systems because their runoff and erosion potentials are high.

25.15.2 Weed Control Problems Related to Soil, Climate, and Tillage Choice

Weed control problems usually increase, at least in initial years, when converting to high residue (CS) systems. With less burial of weed seeds, greater weed emergence seems to be the norm. Grassy weeds like downy brome (*Bromus tectorum*) are particularly favored when tillage is reduced. Furthermore, substitution of sweep tillage for mixing and inverting operations (disks and plows) decreases ease of grassy weed control. The problem is greatest when weeds and crops have the same or similar growth cycles. This is the case with downy brome, which germinates at about the same time that winter wheat is planted. Such weed is especially difficult to control in monoculture systems like continual wheat or wheat-fallow.

Crop rotation is one of the best ways to combat weed problems in any system and this is especially true with reduced tillage and NT. By changing crop type, weeds can be controlled at a different phase of their growth cycle. For example, following wheat (a cool season crop) with a warm season crop (e.g., grain sorghum, sunflower, millet, or corn) provides an opportunity to control weeds that are a problem for wheat.

Herbicides are used to replace part or all of the tillage operations in high residue (CS) systems. Close adherence to specifications for these products is essential to achieve maximum weed control benefits. Also, application methods may need refinement to minimize interception of the herbicide by the residue. Required rates of material can vary with soil texture and OM content. In general, finer-textured soils and those of higher OM content require higher rates of soil-applied herbicides to satisfactorily control weeds than coarse-textured soils. Soil clays and OM inactivate these herbicides and, therefore, rates must be adjusted as prescribed by the manufacturer. Also, caution must be exercised regarding herbicide carryover to the next crop. Coarse-textured, low OM content, and high pH soils are particularly susceptible to carryover problems. Again, applying herbicides at rates no greater than label specifications minimizes these potential problems (Bradford and Peterson, 1999).

When converting to high residue systems, producers must have or must acquire herbicide management skills. Correct sprayer operation from calibration to nozzle type selection is a key requirement to success with residue management systems. New technology, namely, site-specific application for which herbicides are applied only where weeds are present in a field, will greatly aid in judicious use of herbicides (Wilkerson et al., 2004; Goudy et al., 2008).

25.15.3 Surface Residue and Other Conservation Measures

Maximizing snow catch is a vital water conservation measure in dry regions where snow constitutes 20%–50% of the annual precipitation and, therefore, represents a valuable resource for agriculture. Stubble height strongly influences snow catch. Taller stubble retains more snow, but also can increase runoff from snowmelt in spring. Soils that freeze deeply prior to snowfall may be non-conductive to water and, therefore, potentially provide the worst scenario for runoff from snowmelt. With warmer climates like in the central and southern Great Plains, snowmelt is more easily captured because soils do not freeze as deeply and often thaw under the snow; thus, substantial snow and its melt water may be captured after spring thawing occurs. Greb (1979) reported that the efficiency of storing water from snowmelt often is double that of water received as rain.

Contour farming in conjunction with residue maintenance (CS) further maximizes water capture from either rain or snowmelt. Terraces also effectively capture water, but are less necessary on land with good residue cover and contour farming. Obviously, land on slopes >7%–8% may still be best managed with terraces in addition to residue maintenance. Use of contour farming, terracing, and possibly strip cropping in conjunction with CS may be especially important in regions where major high-intensity rainstorms commonly occur and, therefore, may lead to severe soil erosion where only CS, even the NT system, is used.

Maintaining residue on the soil surface by using CS is an invaluable management practice. It enhances water capture and retention, but the cost of storing the additional water with improved residue management can decrease profits if producers are not prepared to effectively and efficiently use the water. Finally, producers should be aware that residue may have negative effects in terms of cold soil temperatures at the time of spring planting. Appropriate system choices including planting method, crop choice, possibly starter fertilizer use, etc. can help ameliorate the potentially negative cold temperature effects.

25.16 Disadvantages

By definition, at least 30% of the soil surface must be covered with residue when the next crop is planted in order to qualify as CS. With NT, a CS method, much greater amounts of residue often are present. Surface residue is highly important for conserving water, controlling erosion, and minimizing environmental pollution under many conditions, but the residue along with the NT method itself also may cause disadvantages under some conditions. Through proper management, most disadvantages usually

can be avoided or overcome, thus generally leading to favorable results when using CS. Potential disadvantages of CS include:

- 1. Conservation tillage involves an increased use of herbicides, which may increase production expenses that are not offset by decreased tillage costs.
- Increased use of herbicides may increase the risk of nonpoint-source pollution, for example, of runoff water and groundwater under some climatic conditions and on some more conductive soils.
- 3. Some weeds are difficult to control with herbicides or have become tolerant of herbicides. As a result, tillage may be required to control such weeds.
- 4. Greater amounts of N fertilizer may be needed when first switching to CS (especially NT) systems; also, reduced N mineralization due to heavy residue mulch can require the use of increased amounts of fertilizers. Changes in fertilizer application methods may be needed when using CS systems and it may be necessary to apply a starter fertilizer under some conditions.
- 5. High earthworm populations and preferential water flow through the deep burrows may cause leaching of agricultural chemicals to depths beyond the reach of plant roots and into groundwater.
- 6. Soil compaction may occur under some conditions, particularly in nearly level and clayey soils, thus requiring occasional tillage or subsoiling to overcome the problem.
- 7. The NT method of CS may not be suitable on hard-setting soils because water infiltration often is lower than where such soils are loosened by tillage.
- 8. The NT method may not always be better than CT on clayey, cold, and wet soils. Cold soil (delayed warming) due to large amounts of surface residue may delay crop planting, reduce the seed germination rate, cause low plant populations, and possibly result in freeze damage if maturity is delayed. Also, reduced runoff and evaporation aggravate excessive water problems on poorly drained soils.
- 9. Leachates from residue of some crops may cause phytotoxicity problems for subsequent crops.
- 10. New crop-planting and herbicide-application equipment may be required, thus initially resulting in additional expenses for the producer.
- 11. Crop planting may be difficult where large amounts of residue are on the surface. For example, NT planting under irrigated conditions at Bushland, Texas, was difficult because the large amount of surface residue kept the clay loam moist, thus causing the soil to severely adhere to the planting equipment (S. Evett, Personal communication, 2008).
- 12. Surface residue provides habitat for some rodents, insects, etc., which may damage some crops.
- 13. Conservation tillage, especially NT, is a major departure from CT and, therefore, requires good management for it to be successful. As a result, special training may be required, which may not be readily available or may entail additional expenses for the producer.

25.17 Conclusions

Conservation tillage, especially the NT method, represents the most dramatic change in soil management for crop production in the history of agriculture. Historically, farmers prepared their whole field as a seedbed, even though seeds were placed only in a small area. Now, major soil disturbance is no longer necessary because only a small area needs to be disturbed to prepare a seedbed or plant seeds. Quite obviously, these changes decrease labor and power requirements for the farmer. By not disturbing most of the soil, fields are kept in a more "natural setting." When disturbance is minimized, soil aggregate integrity is maintained and soil physical, chemical, and biological components respond positively. As a result, water conservation is improved, erosion is minimized, plant nutrients are retained, and soil biological processes proceed with fewer interruptions. The greatest benefits of CS, especially NT, agriculture will be achieved when farmers, technology-transfer persons, and scientists learn how to fully exploit this ecologically beneficial system. NT is a pioneering method of agriculture. The large benefits of NT for minimizing soil erosion, reducing tillage costs, improving soil quality, and many others outweigh the disadvantages associated with this tillage method. Conservation tillage combined with residue mulching, cover crops, crop rotations, and other best management practices is a win-win strategy for soil and water conservation and for sustained agronomic production (Blanco and Lal, 2008).

26.1 Introduction: Why Soil Quality?

Soils are fundamental to the well-being and productivity of agricultural and natural ecosystems. The concept of soil quality was developed to characterize the usefulness and health of soils as a means of evaluating sustainable soil management practices. The concept has been applied throughout the world for a multitude of purposes (e.g., Lamarca, 1996; Ouedraogo et al., 2001; Shepherd et al., 2001; Tian and Feng, 2008). Recent reviews have emphasized the importance and success of the concept for sustainable agriculture and ecological management (Karlen et al., 2001; Wienhold et al., 2004; Kibblewhite et al., 2008), while others have critiqued the concept as counterproductive to the goals of soil science and the challenges of modern agriculture (Sojka and Upchurch, 1999; Singer and Sojka, 2001; Letey et al., 2003; Sanchez et al., 2003; Sojka et al., 2003). This chapter summarizes recent literature on the soil quality concept and touches upon some of the larger issues raised in the course of its discussion.

Since the 1970s, there has been heightened attention paid to the sustainability of human uses of soil based on concerns that soil quality may be declining as global population and pressure on environmental resources increase (Fournier, 1989; Parr et al., 1990; Doran et al., 1996; Boehn and Anderson, 1997). Lal (1995) described the land resources of the world (of which soil is one component) as "finite, fragile, and nonrenewable," and reported that only about 22% (3.26 billion ha) of the total land area on the globe was suitable for cultivation, and only about 3% (450 million ha) had a high agricultural production capacity. Soil as a natural, undisturbed body is in large but finite supply, and the condition of soils in agriculture and the environment is an issue of global concern given the extensive human reliance on soil resources (Howard, 1993; FAO, 1997; Foley et al., 2005; Figure 26.1). Well-known and more recently recognized issues include soil losses from erosion,

maintaining agricultural productivity, protecting natural areas, protecting water quality, adverse effects of soil degradation on human health, and the role and management of soils in the global climate system (Crosson and Stout, 1983; Siegrist, 1989; Denneman and Robberse, 1990; Haberern, 1992; Howard, 1993; Sims et al., 1997; Melillo et al., 2002; Tilman et al., 2002; CAST, 2004; Robertson and Swinton, 2005; Palm et al., 2007; IPCC, 2007). In a general sense, soil quality has effectively become a central issue in the global climate debate because soils regulate greenhouse gases, store carbon, and will require careful management if they are to produce biofuels or effectively sequester carbon (CAST, 2004; Hill et al., 2009). However, despite the importance of understanding and managing the condition of soil resources globally, the goal of evaluating "soil quality" as a measurable attribute at the global scale remains elusive.

Even at a local scale, priorities for assessing soil quality in an agricultural context may be somewhat different from priorities for assessing soil quality in a natural ecosystem. For agriculture, soil quality may be managed to optimize production of a crop without adverse environmental effect, while in a natural ecosystem, soil quality may be managed relative to a baseline condition or potential against which future changes in the system may be compared, and with management decisions structured to maintain the natural potential or function of soils supporting plant communities, animal habitats, etc. This chapter discusses the concept of soil quality for agriculture and the environment and reviews approaches for evaluating soil quality.

26.2 Defining Soil Quality

Useful evaluation of soil quality requires agreement about why soils are important, how soil quality is defined and how it should be measured, and how to respond to soil quality assessments

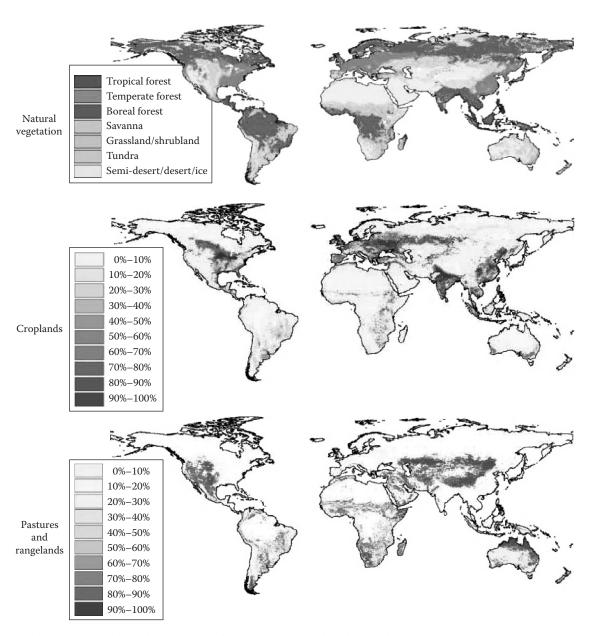

FIGURE 26.1 (See color insert.) Worldwide extent of human land-use and land-cover change. (From Foley, J.A., R. DeFries, G.P. Asner, C. Barford, G. Bonan, S.R. Carpenter, F.S. Chapin, M.T. Coe, G.C. Daily, H.K Gibbs, J.H. Helkowski, T. Holloway, E.A. Howard, C.J. Kucharik, C. Monfreda, J.A. Patz, C. Prentice, N. Ramankutty, P.K. Snyder. 2005. Global consequences of land use. Science 309:570–574.) Croplands are 12% and rangelands are 22%. (From Ramankutty, N., A.T. Evan, C. Monfreda, and J.A. Foley. 2008. Farming the planet: 1. Geographic distribution of global agricultural lands in the year 2000. Global Biogeochem. Cycles 22:GB1003, doi: 10.1029/2007GB002952.)

with management, restoration, or conservation practices. Because evaluating soil quality requires one or more value judgments, and because we have both much to learn about soil and much to lose as a result of poor soil management, these issues are not easily addressed (Sojka et al., 2003; Palm et al., 2007). Gregorich et al. (1994) stated, "Soil quality is a composite measure of both a soil's ability to function and how well it functions, relative to a specific use." This emphasis on use is consistent with the older articulation of "land quality" (FAO, 1976, 1995, 1997; Rossiter, 1996; Sombroek, 1997). However, the relationship between broadly defined soil functions and diverse human uses

of soils can be difficult to comprehensively address (Sanchez et al., 2003). Soil scientists do not all agree that soil quality is a useful concept. For opposing views of the topic, refer to thorough discussions and expansive literature reviews in Karlen et al. (2001) and Sojka et al. (2003).

The soil quality concept was developed as a way to integrate existing and developing ideas about sustainable agriculture and environmental health in the last few decades (Arshad and Coen, 1992; Sheppard et al., 1992; Karlen et al., 1992, 2001; NRC, 1993; Doran and Parkin, 1994; Herrick et al., 2002). Discussion of soil quality invokes issues critical to human survival: the

Soil Quality 26-3

Box 26.1 Three Functions of Soil

oils are living systems that are vital for producing the food and fiber humans need and for maintaining the ecosystems on which all life ultimately depends. Soil directly and indirectly affects agricultural productivity, water quality, and the global climate through its function as a medium for plant growth, a regulator, and partitioner of water flow, and an environmental buffer.

Soils make it possible for plants to grow. Soils mediate the biological, chemical, and physical processes that supply nutrients, water, and other elements to growing plants. The microorganisms in soils transform nutrients into forms that can be used by growing plants. Soils are the water and nutrient storehouses on which plants draw when they need nutrients to produce roots, stems, and leaves. Eventually, these become food and fiber for human consumption. Soils—and the biological, chemical, and physical processes that they make possible—are a fundamental resource on which the productivities of agricultural and natural ecosystems depend.

Soils regulate and partition water flow through the environment. Rainfall in terrestrial ecosystems falls on the soil surface where it either infiltrates the soil or moves across the soil surface into streams or lakes. The condition of the soil surface determines whether rainfall infiltrates or runs off. If it infiltrates the soil, it may be stored and later taken up by plants, move into groundwaters, or move laterally through the earth, appearing later in springs or seeps. This partitioning of rainfall between infiltration and runoff determines whether a storm results in a replenishing rain or a damaging flood. The movement of water through soils to streams, lakes, and groundwater is an essential component of recharge and base flow in the hydrological cycle.

Soils buffer environmental change. The biological, chemical, and physical processes that occur in soils buffer environmental changes in air quality, water quality, and global climate. The soil matrix is the major incubation chamber for the decomposition of organic wastes including pesticides, sewage, solid wastes, and a variety of other wastes. The accumulation of pesticide residues, heavy metals, pathogens, or other potentially toxic materials in the soil may affect the safety and quality of food produced on those soils. Depending on how they are managed, soils can be important sources or sinks for carbon dioxide and other gases that contribute to the greenhouse effect (greenhouse gases). Soils store, degrade, or immobilize nitrates, phosphorus, pesticides, and other substances that can become pollutants in air or water.

Source: NRC (National Research Council), Soil and Water Quality: An Agenda for Agriculture, Committee on Long-Range Soil and Water Conservation, Board on Agriculture, National Academy Press, Washington, DC, 1993.)

environmental cost of agricultural production and grazing, the potential for reclamation of degraded soils, and the sustainability of human land use practices in a larger environmental context. In general, definitions of soil quality have attempted to comprehensively inventory soil functions and relate them to diverse human benefits from soil resources (Box 26.1). In practice, however, the soil quality concept has mainly been applied to agricultural and rangeland management from a local to regional scale.

The definition of soil quality currently used by the Soil Science Society of America (1996; https://www.soils.org/publications/soils-glossary#) is that of Doran and Parkin (1994): "the capacity of a soil to function within ecosystem boundaries to sustain biological productivity, maintain environmental quality, and promote plant and animal health." Other function-based definitions of soil quality have been reviewed and evaluated in Karlen et al. (2001) and Sojka et al. (2003).

Multifunctional soil quality definitions are challenging to evaluate because agricultural and environmental functions (e.g., nutrient status and water quality) may conflict (Sojka et al., 2003), and because our understanding of soil functions and sustainability in the Earth system continues to expand. Since the first

writing of this chapter (Singer and Ewing, 2000), the management of soils for carbon sequestration and greenhouse gas regulation has become a major topic of research and discussion in the global climate debate (e.g., CAST, 2004; IPCC, 2007). We also know a great deal more about atmospheric mobilization and deposition processes affecting soils (reactive N, dust, global transport of pollutants, etc.; e.g., Derry and Chadwick, 2007; Bowman et al., 2008). Development of a biofuels industry will put enormous pressure on soil resources (e.g., CAST, 2008; FAPRI, 2008; Fargione et al., 2008; Searchinger et al., 2008; Hill et al., 2009; Tilman et al., 2009). Agricultural and land management practices are coming under increased scrutiny as these connections are drawn (Tilman et al., 2002; Foley et al., 2005; Robertson and Swinton, 2005; Rockstrom et al., 2009a, 2009b). The challenge for soil resource management lies in connecting what we know and value about soils with how we realistically manage the demands of carbon regulation and food and energy production that we now face with agricultural and other land management choices, and the pressures of a growing population on both agricultural and natural systems (Tilman et al., 2002; Foley et al., 2005; Gomiero et al., 2008; Goulding et al., 2008; Rockstrom et al., 2009a). A multifunctional view of soils is critical for evaluating global ecological management goals that incorporate human and societal well-being (MEA, 2005; Palm et al., 2007).

26.2.1 Soil Quality as Soil Function

The 1993 National Research Council report "Soil and water quality: An agenda for agriculture" (NRC, 1993) articulated the soil quality concept in the United States, basing it firmly in agriculture (Box 26.1; Figure 26.2). Yet the report included natural systems in its justification, finding that "...national policies to protect soil resources should be based on the fundamental functions that soils perform in natural and agroecosystems." It is worth noting that this evaluation of soil functions is fundamentally different from the philosophy of soil taxonomical classification in the U.S. system, which seeks to characterize the diversity of soils by properties observable in a field setting or with limited laboratory analysis, without the interpretation required to

assess soil functions. A limitation of the U.S. taxonomy—or any descriptive system—is that it does not address soil degradation, which can only be successfully evaluated in terms of ecological functions broadly defined (MEA, 2005; Foley et al., 2005; Palm et al., 2007). Recent work has sought to unify soil taxonomic mapping with the evaluation of soil degradation (Tugel et al., 2005; Palm et al., 2007; Sanchez et al., 2009).

The functions of soils within agricultural and natural ecosystems can be characterized as ecosystem services (Cassman, 1999; Table 26.1) that are intimately tied to human and societal wellbeing (Figure 26.3) (Tilman et al., 2002; MEA, 2005; Robertson and Swinton, 2005; Palm et al., 2007; Kibblewhite et al., 2008; Carpenter et al., 2009). Increases over the last 40 years in agricultural production—in terms of both yield and cultivated land area—have come with trade-offs that include soil degradation, that is, reduction of many of the regulatory and supporting services in which soils play a central role (Figure 26.4) (Foley et al., 2005; Palm et al., 2007; Carpenter et al., 2009). Issues of sustainable

Soil Quality 26-5

TABLE 26.1 Relationships among Provisioning Ecosystem Services, Soil Processes and Properties, and Core Soil Determinants

Provisioning Ecosystem Service	Ecosystem/Soil Process	Soil Property	Core Soil Determinants
Physical support for plants	Soil formation	Depth, texture, structure	State factors of soil formation, clay mineralogy
Provision of nutrients/	Mineral weathering	Mineral distribution	Parent material
biogeochemical cycles	Soil organic matter mineralization	Soil organic matter quantity and quality	Texture, water balance
	Decomposition of organic additions	Soil biota	Texture, water balance
	Ion retention and exchange	Effective cation and anion exchange capacity	Texture, mineralogy, soil organic matter
	Toxicities	Percent Al saturation, electrical conductivity, percent exchangeable Na, toxic levels of Fe, Mn, B	Clay mineralogy, pH
Provision of water	Infiltration	Surface macroporosity, hydraulic conductivity	Aggregation, texture, bulk density, soil organic matter, soil biota
	Storage in soil	Aggregation, bulk density, depth	Texture, mineralogy, soil organic matter
	Drainage	Macroporosity, hydraulic conductivity	Texture, mineralogy, soil organic matter

Acad. Sci. 106:1305–1312.)

soil management, soil degradation, and soil resilience are central to the soil quality concept, and are further discussed below. Our review of the literature suggests that these issues have been more forcefully articulated independently of the formalized concept of "soil quality." Yet the need for the soil expertise in discussion of these issues and in global change science has never been greater.

26.2.2 Soil Quality Is Not a New Idea

Soil quality has historically been equated with agricultural productivity in the United States, whereas in Europe, the concept was developed to address soil pollution. Soil conservation practices to maintain soil productivity are as old as agriculture itself, with documentation dating to the Roman Empire (Jenny, 1961). Beginning in the 1930s, soil productivity ratings were developed in the United States and elsewhere to help farmers select crops and management practices that would maximize production and minimize erosion or other adverse environmental

effects (Huddleston, 1984). The Storie Index (Storie, 1932, 1964) and the USDA Land Capability Classification (Klingebiel and Montgomery, 1973) were developed to separate soils into different quality classes based on inherent and "static" soil properties such as depth to a restrictive layer. These rating systems are important predecessors of more recent attempts to quantitatively assess soil quality. In the 1970s, attempts were made to identify and protect soils of the highest productive capacity by defining "prime agricultural lands" (Miller, 1979; Reganold and Singer, 1979; Singer et al., 1979). Alexander (1971) suggested developing soil quality criteria. Warkentin and Fletcher (1977) followed by introducing a soil quality concept based on dynamic soil properties relating to organic matter and biology, which sought to improve upon evaluations based solely on productivity and erosion control. Carter et al. (1997) articulated the distinction between "static" and "dynamic" aspects of soil quality. Farmers typically consider both in a working evaluation of soil health—a term often used interchangeably with soil quality (Romig et al., 1995; Table 26.2).

Soil Quality 26-7

TABLE 26.2 Soil Health Properties Derived from Farmer Interviews

		Description		
Rank	Soil Health Property	Healthy	Unhealthy	
1	Organic matter	As high as possible, at soil's potential, manure, compost >3%, 2%, 7%–8%, putting more back	Rough, lack of organic matter, less, low	
2	Crop appearance	Green, healthy, uniform, lush, dense stand, tall, larger, sturdy, stout, proper color, darker, good crop	Yellow, stunted corn, small, poor color, poorer, lack of green, light green, streaks in field	
3	Erosion	Would not erode, water, and wind not taking soil, prevented, stays in place, less, slowed down, delayed	Blows sooner, washes, topsoil is lost, erodes more, clouds of dust, ravines, runs bad, any, easier	
4	Earthworms	Fishing and red worms present, see after rain, a lot, angle worms, see holes and castings, see during plowing	Not there, do not work, cannot find, no holes, lack of, killed by insecticides or anhydrous, void	
5	Drainage	Water goes away, fast, better, no ponding, moves through, takes a lot of rain, drains properly, dries out	Tight, waterlogged, drains too fast, ponding, no outlet for water, will not drain, slop, poor, saturated	
6	Tillage ease	One pass and ready, breaks up, mellow, easier, smooth, crumbles, flows, plow a gear faster, minimum	Never works down, needs more disking, lumps, slabs, shiney, pulls hard, worked wet, overworked	
7	Soil structure	Will not roll out of hand, crumbly, loose, holds together, granular	Hard, does not hold together, lumpy, falls apart, massive, cloddy, lumpy, clumpy, tight, compacted, powder	
8	pН	7.0, 6.7-6.8, 6.2-6.7, balanced, neutralize	<6.0, high, nothing works, wrong, too low, high acidity	
9	Soil test	Up to recommendations, high, elevated, complete, where it belongs, every year or two, stay up with soil test	Law of minimum at work	
10	Yield	9.5–11.5 Mg ha $^{-1}$ com, 4 Mg ha $^{-1}$ soybeans, 30%–40% higher, +0.7 Mg ha $^{-1}$, better 5 years average, significantly higher	7 Mg ha ⁻¹ com, 9.5 Mg ha ⁻¹ corn, 2.5 Mg ha ⁻¹ soybeans, 20%–50% less, do not get much off, down, reduced, low	
11	Compaction	Does not pack down, not compacted, stays loose, not out there when wet	Compacted, plow layer, packs down, hardpan, plowsoil, tight, cannot get into it, packed	
12	Infiltration	Water does not stand, absorbs, water moves into soil, soaks, rapid, no ponding, fast, spongy	Water runs off soil, sits on top, water stands, does not absorb, puddles, nonporous	
13	Soil color	Dark, black, dark brown, gray, holds dark color	Orange, brown, light, white, red, blue-gray, subsoil color, bleached, sandy colored, light brown, pale, anemic, gray	
14	Nitrogen	Put on less, manure, as required, compost, slurry, more available, organic N, organic matter	Too much N, chemical N, commercial fertilizers burn ground, anhydrous, sludge	
15	Water retention	Holds moisture, get by with less, retains more, moisture travels, gives and takes water freely, conserving	Too much water, does not hold water, dries out, too wet or dry, droughty, stays wet, runs out of moisture, poor	
16	Phosphorus	As required	_	
17	Nutrient deficiency	Has what it needs, no shortage of elements, no spots on leaves	Yellow, purple, discoloration in leaves, lodging, crop falls off, stripping, brown streaks, firings on bottom, blight	
18	Decomposition	Breaks down, decays, rots in 4–5 months, manure part of soil in 1 year, disappears, not too fast, 2/3 gone in year	See stalks from last year, does not break down, manure plows up next year	
19	Potassium	As required	_	
20	Roots	Larger, spread out, grown down, white, deep, numerous, good penetration, full, lots of feeders, branched out	Do not penetrate, undeveloped, balled up, grow crossways, discolored, diseased, at hard angles, shallow, short

Many attempts to define soil quality and to develop indices to measure it have been similar to earlier soil productivity ratings (Doran and Parkin, 1994; Doran and Jones, 1996; Snakin et al., 1996; Seybold, et al., 1997; Karlen et al., 2001; Sojka et al., 2003). As the soil quality concept has evolved, researchers have moved from qualitative definitions to more quantitative models that combine diverse variables and spatial characteristics of soils. They have also moved from assessing static properties to those that are dynamic (Sanchez et al., 2003; Tugel et al., 2005; Tugel et al., 2008). By the 1990s, soil quality had become a national policy in several countries. In 1990, the Canadian Soil Quality Evaluation Program was initiated, and benchmark sites established for long-term monitoring (Walker et al., 1997). In New Zealand, the 1991 Resource Management Act required sustainable land management practices

(Lilburne et al., 2002). In 1994, the U.S. Soil Conservation Service was reorganized as the Natural Resources Conservation Service, and the Soil Quality Institute (http://soils.usda.gov/sqi/) was created within NRCS "to cooperate with partners in the development, acquisition and dissemination of soil quality information and technology to help people conserve and sustain our natural resources and the environment."

26.2.3 Agricultural Productivity and Sustainability

To many in agriculture and agricultural research, productivity is still the primary indicator of "soil quality" because it is the net result of soil degradation processes and soil conservation

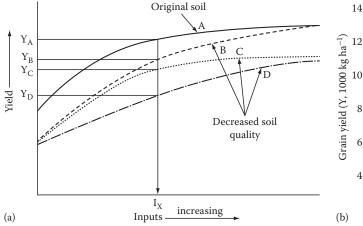

practices (Parr et al., 1990). Worldwide, agriculture is the most extensive human land use, amounting to ~35% of the land area on Earth (Foley et al., 2005; Ramankutty et al., 2008; Figure 26.1) and including irrigated and rain fed cultivated cropland, permanent crops, such as orchards and vineyards, irrigated pasture, range, and managed forests. Each cropping system has distinct soil and soil management conditions for optimal production.

Since the early 1960s, the world population has doubled, and global food production has increased by 145% (Pretty, 2008). Of that increased food production, ~70% has been through intensification of agricultural yields rather than through expansion of production area (MEA, 2005; Pretty, 2008). At the same time, increasing meat consumption has led to increasing intensity of livestock production through use of inexpensive grains for feed in concentrated animal feeding operations (CAFOs) (Tilman et al., 2002; Thorne, 2007; Pretty, 2008). In industrialized countries, ~70% of cereal products are now used for animal feed (Pretty, 2008). Intensification of livestock production at CAFOs has raised concerns about sustainability given resources used for feed, increased disease incidence related to these operations, and pollution due to concentrated animal waste (Thorne, 2007). Moreover, long-term yield declines in high-input cereal cropping systems suggest slow degradation of highly productive soils (Cassman, 1999; Cassman et al., 2003).

Sustaining food production for the world's growing population will require careful evaluation of the relationship between soil quality (degradation) and yield (productivity) (Cassman, 1999; Cassman et al., 2003) (Figure 26.5a). It has recently been

argued that at the global scale, loss of high-productivity land to degradation, biofuel production, or urbanization could lead to widespread agricultural expansion into marginal lands with lower yields and higher risk of degradation (Rockstrom et al., 2009b). Evaluating soil quality vs. yield is part of optimizing management practices to sustain increases in food production while optimizing efficient use of inputs (N, water) and C sequestration, and minimizing greenhouse gas emissions (Cassman et al., 2003) (Figure 26.5b).

The resources available to farmers dictate strategies for increasing agricultural productivity and the ability to manage soil quality for agriculture (Cassman, 1999). In the United States, resources may be readily available for management of dynamic soil properties such as nutrient or water status. In other countries, farmers may be resource poor, and agricultural systems are generally low input, meaning that large-scale irrigation is absent, use of fertilizers, pesticides, and herbicides is minimal, and high energy, mechanized equipment is not available (Eswaran et al., 1997). Under these circumstances, soil quality for agriculture will depend more on climate than if the same soils were part of a highly managed, irrigated system (Eswaran et al., 1997). Increases in agricultural production must come primarily through increases in production area rather than yield. In sub-Saharan Africa, for example, two thirds of increased production in the last 40 years has come from agricultural expansion (MEA, 2005). In low-input agriculture, sustainability is more dependent on maintenance of inherent soil fertility and other attributes, because resources may not exist to remedy soil degradation (Sanchez et al., 2003).

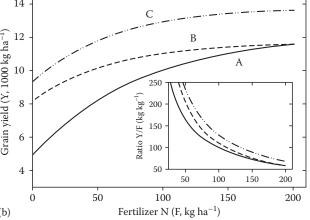

FIGURE 26.5 (a) Conceptual model illustrating the relationship between crop yields and input requirements as influenced by soil quality. (From Cassman, K.G. 1999. Ecological intensification of cereal production systems: Yield potential, soil quality, and precision agriculture. Proc. Natl. Acad. Sci. 96:5952–5959.) A decrease in soil quality from an initial state (curve A) can result in the need for greater inputs of energy, nutrients, water, seed, and pest control measures to achieve the same yield. The slope and asymptote of the shifted response (shown by curves B, C, and D) depend on the type of soil degradation and can result in a reduction in input use efficiency, yield potential, or both. (b) Hypothetical relationship between maize yield (Y) and the N application rate (F) for average soil quality and average yield (curve A), average yield and increased soil organic matter content and associated indigenous N supply (curve B), and increased soil organic matter content and indigenous N supply with improved crop management to achieve greater N fertilizer efficiency at all rates of applied N (curve C). Scenarios B and C assume an increase of 50 kg N ha⁻¹ in indigenous N supply from the increase in soil organic matter. Insert shows the overall N use efficiency (Y/F) for each scenario. (From Cassman, K.G., A. Dobermann, D.T. Walters, and H. Yang. 2003. Meeting cereal demand while protecting natural resources and improving environmental quality. Annu. Rev. Environ. Resour. 28:315–358.)

The ability to irrigate also has a profound impact on management of soil resources for food production. One-third of the total global harvest of food comes from the 17% (255 million ha) of the world's cropland that is irrigated (Hoffman et al., 1990; Gleick, 1993; Doll and Siebert, 2002), three quarters of which is in developing countries (Tribe, 1994; Doll and Siebert, 2002; FAO, 2008). The area of cropland that is irrigated doubled between 1961 and 2002 (Pretty, 2008), with the greatest area of irrigated land in India, China, the United States and Pakistan (Vorosmarty et al., 2000; Doll and Siebert, 2002; FAO, 2008; Wisser et al., 2008). Sojka (1996) suggested that the arid and semiarid soils that support most irrigated agriculture have thin erodible surfaces, characteristics that could classify such soils as having poor quality. Yet under irrigation, they feed much of the world. Without irrigation, for example, in many African soils, moisture stress becomes a significant factor limiting production, and the water holding capacity of a soil becomes crucial (Eswaran et al., 1997; Cassman et al., 2003; Sanchez et al., 2003).

These practices associated with cultivation dictate regionally specific soil management strategies. Yet soils that are not cultivated are a much larger component of agriculture, broadly defined, than those that are cultivated. About 65% of the land in the United States is forest (284 million ha) or rangeland (312 million ha), with only about 284 million ha cultivated (NRC, 1994). Herrick and Whitford (1995) suggested that rangeland soils, which often serve multiple uses, present unique challenges and opportunities for assessing soil quality because spatial and temporal variability are higher than in cropped systems. On rangelands and forestlands, food, fiber, timber production, biomass for fuel, wildlife, biodiversity, recreation, and water supply are all potential uses that may have diverse criteria for quality soils.

In the past, many of the arguments about the sustainability of agricultural systems have related to the form in which nutrients are most sustainably returned to soils. Increasing pressure on soil resources globally has made it clear that no agricultural system will be sustainable in the long run without management that considers larger scale nutrient cycling, water use, and energy budgets (Tilman et al., 2002; Cassman et al., 2003). Increasing yields typically require more energy and resources, although increased efficiencies of water, fertilizer, and other input use are possible (Tilman et al., 2002; Pretty, 2008). Yet the sustainability of tradeoffs inherent in all decisions about soil and land management must ultimately be evaluated with respect to larger human benefits including opportunity, security, and health (McMichael et al., 2003). Soil fertility and resilience are among ecosystem services that profoundly benefit all of human society. Excessive human exploitation of ecosystem services, including soil quality undermines the capacity of the biosphere to both sustain food production and provide a continued flow of other goods and services essential to long-term human survival, including maintenance of freshwater resources, regulation of climate and air quality, and amelioration of infectious diseases (McMichael et al., 2003; Foley et al., 2005). It has been argued that in the interest of balancing the regulatory and provisioning functions of soils globally, a limit on cultivated land area must be set at 15% (cultivated area is now 12%; Rockstrom et al., 2009b). As we consider global limits on food production, the management of finite soil resources for adequate yields and sustained soil quality is clearly critical (Cassman et al., 2003).

Thus, while our need for sustainable soil management only increases with time, in some respects, the lesson of the soil quality debate has been that an increasingly urban population (Pretty, 2008) is increasingly ignorant of soil conservation practices known since the beginning of agriculture. Our collective ability to practice sustainable soil management diminishes in the face of exploitative agricultural capabilities and the culinary and energy demands of urban society. The "soil quality" concept emerged in wealthy, industrialized countries following the rise of organic farming and the sustainable agriculture movement, which has largely catered to urban populations looking to remedy the real and perceived environmental ills of modern agriculture through purchasing choices. The underlying issues of true sustainability and widespread soil degradation are profound and of global importance (Rockstrom et al., 2009b, Sanchez et al., 2009). The application of "soil quality" evaluation to rangeland management in the western United States (summarized below) is evidence that all land and ecosystem management choices rely on sustainable soil management. Yet the specifics of formalized "soil quality" evaluation have remained parochial (Sanchez et al., 2003; Palm et al., 2007). There is a real and pressing need to apply the strongest aspects of the soil quality discussion to the goal of sustainable soil, land, and ecosystem management (Cassman et al., 2003; Foley et al., 2005; Palm et al., 2007).

26.2.4 Rangeland Health

Soil quality is a component of rangeland health (NRC, 1994; Herrick et al., 2002; Pyke et al., 2002; Herrick et al., 2005a, 2005b; Pellant et al., 2005). In 1994, the NRC defined rangeland health as "...the degree to which the integrity of the soil and the ecological processes of rangeland ecosystems are sustained," and recommended a coordinated national monitoring effort by the USDA, DOI, and EPA. Soil integrity was defined primarily in terms of susceptibility to erosion, as "the capacity of the site to limit redistribution and loss of soil resources (including nutrients and organic matter) by wind and water" (USGS, 2002). Herrick et al. (2002) recommended an integrated approach for soil quality and rangeland monitoring. They proposed site-specific indicators closely tied to resource concerns, generally soil and site stability, hydrologic function, and biologic integrity. They emphasized an understanding of spatial variation in relating indicators to ecological functions as well as nonlinearity of indicator response and threshold effects in monitoring and managing ecological systems. This approach is developed in subsequent interagency guidelines for assessing rangeland health in the United States (Herrick et al., 2005a, 2005b; Pellant et al., 2005). The same fundamental priorities of preventing erosion and maintaining site productivity are evident in the assessment of soil quality indicators in Iranian rangelands (Rezaei et al., 2006).

26.2.5 Soil Degradation and Resilience

Soil degradation has been defined as "a reduction in soil quality as a result of human activities" (Cassman, 1999) and as "the adverse changes in soil properties and processes leading to a reduction in ecosystem services" (Palm et al., 2007). The increased provisioning of food, fuel, and fiber realized over the past 40 years has resulted in the degradation of soils and the ecosystem services they provide (Palm et al., 2007). Salinization causes the loss of ~1.5 million ha of arable land per year, and up to 40% of global croplands—mostly in developing countries—may also be experiencing some degree of degradation due to erosion, reduced fertility, or overgrazing (Cassman, 1999; Foley et al., 2005). Erosion continues to be a primary adverse human impact on soils (Pimentel et al., 1995; Sojka et al., 2003; Montgomery, 2007), affecting over 80% of degraded soils (Cassman, 1999). Moreover, downstream effects of soil erosion and increased fertilizer use can be profound (Pimentel et al., 1995; EEA, 1999, 2005; Foley et al., 2005).

Willis and Evans (1977) had the problem of soil erosion in mind when they argued that soil is not renewable over the short term based on studies that suggest that 30 to more than 1000 years are required to develop 25 mm of surface soil from parent material by natural processes. Jenny (1980) also argued that soil is not renewable over the time scale to which humans relate. Yet under less extreme circumstances of soil degradation such as contamination or loss of fertility, some soil functions can be restored even if the original, natural state of the soil cannot be entirely recreated. For agriculture, some important (dynamic) soil characteristics are slowly renewable through management practices. Organic matter, most nutrients, and some physical properties may be renewed through careful long-term management. Certain chemical properties (pH; salinity; N, P, K content) may be altered to a more satisfactory range for agriculture within a growing season or two, while immobilization or bioremediation of unwanted chemicals may depend strongly on the interaction of management techniques and intrinsic soil properties.

However, the consequences of soil degradation may be most dire in the tropics, where resources for soil rehabilitation are limited and primary concerns include food insecurity and rural poverty tied to inadequate nutrient inputs to maintain soil fertility (Sanchez, 2002; Sanchez et al., 2003; Virtuosic et al., 2009). The soil quality concept was developed in temperate regions to address environmental issues arising from agricultural systems with large nutrient and energy inputs (Sanchez et al., 2003). While the holistic approach implicit in debate about the soil quality concept is relevant to all regions, work in the tropics has shown that useful assessment of sustainable soil management and rehabilitation practices requires informed simplification of goals and prioritization of measured attributes (Sanchez et al., 2003). Arguably, what is needed for better global management of soil resources is improved global mapping of soil taxa, function, and degradation (Tugel et al., 2005; Sanchez et al., 2009).

The capacity of soil to recover its structural and functional integrity after a disturbance has been called soil "resilience"

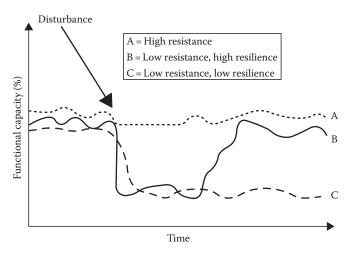

FIGURE 26.6 Soil function, disturbance, resistance, and resilience. (From Tugel, A., J.E. Herrick, J.R. Brown, M.J. Mausbach, W. Puckett, and K. Hipple. 2005. Soil change, soil survey, and natural resources decision making: A blueprint for action. Soil Sci. Soc. Am. J. 69:738–747.)

(Blum, 1994; Seybold et al., 1999; Figure 26.6). It has been argued that the stability and resilience of soils upon disturbance is not well understood, and, hence, that soil degradation is poorly characterized from regional to global scales (Palm et al., 2007). In ecology, the concept of ecosystem resilience was developed starting in the 1970s, leading to the idea of alternative stability states and "catastrophic shifts" in major ecosystems as a result of climate change or other perturbation (Scheffer et al., 2001). An example is an irreversible change in a plant community resulting from soil degradation due to grazing (van de Koppel et al., 1997). Key points in this thinking are that disturbance is a natural component of ecosystems that promotes diversity and renewal, and that soil properties are a primary factor in ecosystem resilience against disturbance (Scheffer et al., 2001; Folke et al., 2004; Rockstrom et al., 2009b). Hence, soil functions and land use are a major component of successful ecosystem management to maintain ecosystem services critical to human survival (Folke et al., 2004; Foley et al., 2005; Ellis and Ramankutty, 2008; Carpenter et al., 2009). The limits of agricultural productivity and the regulatory capacity of the Earth system must somehow be considered at a global scale in evaluating sustainable soil management choices (Rockstrom et al., 2009a, 2009b).

Buffering is a function related to soil resilience. The term "buffer" refers collectively to processes that constrain shifts in the dissolved concentration of any ion when it is added to or removed from the soil system (Singer and Munns, 2006). Soils "buffer" nutrients as well as contaminants and other solutes, via sorption to or incorporation into clay and organic materials. The extent to which a soil immobilizes or chemically alters substances that are toxic, thus effectively detoxifying them, reflects "quality" in the sense that humans or other biological components of the system are protected from harm. This is the basis for the concept of soil quality developed in Europe (Moen, 1988; Siegrist, 1989; Denneman and Robberse, 1990). Lack of soil buffering results in direct toxicity or contamination of air or water.

Identifying substances that qualify as "contaminants" can be challenging because some, such as nitrates and phosphates, are important plant nutrients as well as potential water pollutants. An example is agricultural runoff containing nitrate or soluble phosphorus (Yli-Halla et al., 1995).

Holden and Firestone (1997) defined soil quality in this context as "the degree to which the physical, chemical, and biological characteristics of the soil serve to attenuate environmental pollution." Howard (1993) defined the ecological risk of a chemical in the environment as "the probability that a random species in a large community is exposed to a concentration of the chemical greater than its no-effect level." The extent to which a soil is capable of reducing the probability of exposure is a measure of its quality and hence in some sense a component of its "resilience."

A well-studied example of a common soil contaminant is lead (Pb) (McBride et al., 1997). Although legislated limits may be on a concentration basis in soil (e.g., 500 µg kg⁻¹), risk assessment techniques have attempted to account for the chemical form of Pb present, as well as the observed relative relationship between the amount of Pb present in soil and blood levels in local residents (Bowers and Gauthier, 1994). Critics have questioned analytical techniques used to determine bioavailable levels of Pb in soil as well as the degree to which toxicity data account for its chemical fate and ecologically damaging properties (Cook and Hendershot, 1996). Natural variability of soils and variation within a soil series make average values or average background values inadequate for soil quality assessments. In addition, bioaccumulation and toxicity need to be considered when establishing levels of toxicants that may not be exceeded in a "high-quality" soil for a given use (Jongbloed et al. 1996; Traas, et al. 1996). Speir et al. (1996) proposed an "ecological dose value" that represents the inhibitory effects of a heavy metal (in this case Cr(VI)), based on the kinetics of soil biological properties, and serves as a generic index for the determination of permissible concentration levels for heavy metals in soils. Lair et al. (2007a, 2007b) showed that long-term management of soil organic matter in Sweden led to differential sorption of metals among treatments (e.g., manure vs. chemical fertilizer).

26.2.6 Reference States for Soil Quality

Ultimately, any assessment of soil quality must be made relative to desired functional outcomes or management goals. Granatstein and Bezdicek (1992) considered whether the standard reference state of a soil in agricultural systems should be "native" soil conditions or conditions given maximum agronomic, environmental, and economic performance. Seybold et al. (1997) considered three potential baseline values (reference points) for soil quality: the native, the intensively managed, and the altered (reclaimed) states. Given that native conditions may be unknown or difficult to determine, standard conditions for agricultural systems could be based on high-yielding, low environmental impact systems using progressive management practices that do not degrade soils over the longer term. This

designation requires careful evaluation of yield potential vs. soil quality (Cassman et al., 2003; Figure 26.3). Natural systems may be compared to observed baseline or potential states, considering previous human influences or other disturbance (Habich, 2001).

Historical analyses of land use and soil property trends are a means of assessing soil degradation relative to some initial state (Lindert et al., 1996a, 1996b). Studies comparing uncultivated forest and range soils with cultivated soils also provide a measure of the effects of cultivation on soil quality (e.g., Velasquez et al., 2007). A number of studies have found lower organic C and N in cultivated vs. uncultivated soils (e.g., Amundson, 2001; Miller et al., 2004; Golchin and Asgari, 2008) depending on management practices (Olson, 2007). Others have observed increases in soil organic C and N following conversion from agricultural management back to uncultivated land (Poulton et al., 2003; McLauchlan, 2006). These studies have important implications for climate regulation and land management strategies for global sustainability (Rockstrom et al., 2009b).

Baseline values of soil properties have been determined using long-term research plots in many parts of the world (Rasmussen et al., 1998; Richter et al., 2007), including Canada (Beke et al., 1994; Bremer et al., 1994; Biederbeck et al., 1996; Zentner et al., 2001), China (Wu et al., 2004; Ding et al., 2007), Denmark (Schjønning et al., 1994, 2005; Munkholm et al., 2002), England (Johnston, et al., 1986; Jenkinson et al., 1994), Germany (Merker, 1956), India (Masto et al., 2008), New Zealand (Murata et al., 1995; Lilburne et al., 2002), Nigeria (Oluwatosin et al., 2008), Sweden (Gerzabek et al., 1997; Gerzabek et al., 2001; Kirchmann et al., 2004; Gerzabek et al., 2006), Switzerland (Fließbach et al., 2007; Birkhofer et al., 2008), and the United States (Odell et al., 1984; Varvel et al., 2006; Khan et al., 2007). These studies have shown how management of inputs, crop rotation, and tillage practices can change the physical, chemical, and biological properties of soil. In considering soil management strategies for agriculture globally, these studies and others provide important constraints on climate regulation and potential productivity vs. degradation of soil resources (Cassman et al., 2003; Sanchez et al., 2009; Rockstrom et al., 2009b).

26.2.7 Global Climate and Energy Production

As the potential climate effects of rising atmospheric CO₂ gained public attention in the 1990s, the potential for carbon sequestration and hence climate mediation by soils through agricultural management practices was recognized (Schlesinger, 1999; Amundson, 2001; Lal, 2004). This concept dovetailed with ideas presented here (Table 26.3) of soil quality based on organic matter content and fertility, facilitated by management practices favored for sustainable agriculture, such as manuring, crop rotation, and reduced tillage (Tilman et al., 2002; Cassman et al., 2003; West and Post, 2002). The potential for carbon sequestration in soils has motivated the renewed examination of the effects of agricultural management practices on soil organic carbon (e.g., West and Post, 2002; Liu et al., 2006),

TABLE 26.3 Soil Quality, Management, and Climate

Soil Functions/Ecosystem Services ^a	Agricultural and Human Health Management Goals ^b	Influence of Climate Change ^c
Food and fiber production	Increasing yields	Shifting yields: increase in currently colder regions, decrease in mid-latitudes
Nutrient cycling	Increasing nutrient use efficiency	Positive feedback from GHG production by agricultural
Atmospheric composition and climate control	(precision agriculture)	practices; mitigation by changing land management
	Maintaining and restoring soil fertility	practices to sequester C, reduce N ₂ O and CH ₄ emissions
Water relations	Increasing water use efficiency	Drought effects in currently productive regions, e.g., Central
Water quality and supply		Valley of California
Physical stability and support	Increasing yields	Damage to crops and soil erosion due to increased intensity
	Erosion control	of storm events, rising sea level, continuation and/or expansion of conventional tillage
Filtering and buffering	Reduce exposure to pollutants	Change external variables influencing soil resilience
Pollutant attenuation and degradation	Disease and pest control	
Resistance and resilience		
Biodiversity and habitat		

^a Andrews et al. (2004); Kibblewhite et al. (2008).

with additional awareness of global N dynamics (e.g., Gerzabek et al., 2001; Neff et al., 2002). However, efforts to quantify agricultural C sequestration potential face methodological issues associated with the use of average yields and average management practices in field experiments, as well as underestimates of biomass turnover that have kept models from accurately predicting the C sequestration effects resulting from changes in crop management and climate (Cassman et al., 2003). It has been argued that the finite and uncertain potential for carbon sequestration by agriculture is unlikely to significantly offset fossil fuel consumption in the developed world (Lal, 2008), and carbon sequestration potential may itself be offset by the associated production of greenhouse gases, such as N2O (Cassman et al., 2003). Substantial uncertainties remain about the design of optimal management practices to sustain increases in food production while optimizing N use efficiency and C sequestration, and minimizing greenhouse gas emissions; arguably, resolution of these uncertainties will require improved field studies at production scale, using progressive management practices (Cassman et al., 2003).

Nonetheless, soil management practices for both increased carbon storage and reduced greenhouse gas production (CO₂, CH₄, N₂O)—with increased yields through nutrient and water use efficiency—have been proposed for the mitigation of global climate change effects, along with the development of energy crops to replace fossil fuels (CAST, 2004; Hutchinson et al., 2007; IPCC, 2007). Debate about the relative merits of various candidate biofuel crops has led to comprehensive analysis of the environmental and health costs of biofuel production and use (e.g., Hill et al., 2006; Donner and Kucharik, 2008; Landis et al., 2008; Moebius-Clune et al., 2008; Schmer et al., 2008; Hill et al., 2009; Melillo et al., 2009; Tilman et al., 2009). Arguably, an approach focusing on carbon and energy balances provides a more complete evaluation of the environmental costs

and benefits of agriculture (Cassman et al., 2003), yet agricultural policies to address concerns raised by this approach are still lacking in the United States and elsewhere (Robertson et al., 2004; Robertson and Swinton, 2005; Lant et al., 2008), and true sustainability remains elusive (Tilman et al., 2002; Cassman et al., 2003; McMichael et al., 2003; Pretty, 2008: Rockstrom et al., 2009a).

Development of biofuels is just one aspect of soil- and land-based energy production receiving increased attention in the current energy debate (e.g., Tilman et al., 2009), along with other sources such as wind and solar power. These efforts to move energy production from subsurface resource extraction to highly visible and spatially extensive solar panels, turbines, and energy crops at the earth's surface will increase pressure on soil resources and ecosystems both directly and indirectly through changing land use patterns (Melillo et al., 2009). These pressures are likely to further test our ability to sustainably manage soil resources.

26.3 Evaluating Soil Quality

The definition of soil quality and the selection of soil characteristics needed to evaluate soil quality continue to evolve (Idowu et al., 2008; Kibblewhite et al., 2008). Bouma (1989a) recognized that an essential problem with definitions that produce carefully limited suitability classes is that empirical decisions must be made to separate the classes along what is essentially a continuum. Nonetheless, evaluation of soil conditions remains a critical exercise globally (Sanchez et al., 2009).

26.3.1 Selecting Soil Quality Indicators

Carter et al. (1997) suggested a framework for evaluating soil quality that includes (1) describing each soil function on which

^b Tilman et al. (2002); Montgomery (2007); Cassman (1999); Cassman et al. (2003).

c IPCC (2007).

quality is to be based, (2) selecting soil characteristics or properties that influence the capacity of the soil to provide each function, (3) choosing indicators of characteristics that can be measured, and (4) using methods that provide accurate measurement of those indicators.

No soil property is permanent, but rates and frequency of change vary widely among properties. Soil properties also vary with ecosystems, arguably depending mostly on climate. In rangelands, for example, temporal variability is high and relatively unpredictable due to the strong dependence of soil properties on soil moisture (Herrick and Whitford, 1995).

Arnold et al. (1990) suggested that changes in soil properties can be nonsystematic, periodic, or trend. Carter et al. (1997) distinguished between dynamic soil properties that are most subject to change through human use and are strongly influenced by agronomic practices, and intrinsic or static properties that are not subject to rapid change or management.

Examples of dynamic soil characteristics are the size, membership, distribution, and activity of a soil's microbiological community; the soil solution composition, pH, and nutrient ion concentrations, and the exchangeable cation population. Soils respond quickly to changes in conditions such as water content. As a result, the optimal frequency and distribution of soil measurements vary with the property being measured.

Soil mineralogy, particle size distribution, and soil depth are static soil quality indicators. Although changes occur continuously, they are slow under natural conditions. Other soil physical properties such as aggregate stability and hydraulic conductivity are spatially and temporally highly variable (Moebius et al., 2007). Organic matter content may be a dynamic variable, but the chemical properties of organic matter may change only over periods on the order of 100–1000 years depending on texture.

Soil properties that change quickly present a problem because many measurements are needed to determine an average value and to evaluate whether changes in the average indicate improvement or degradation of soil quality. Conversely, properties that change very slowly are insensitive measures of short-term changes in soil quality. Papendick et al. (1995) argued that the minimum data set (MDS) required for soil quality analysis includes a mix of "dynamic" and relatively "static" properties.

A soil quality assessment must specify area. One could use the pedon (the three-dimensional soil individual) as the unit of measure, or a soil map unit component, a landscape, a field, or an entire watershed. The choice will depend to some degree on what property is of interest and spatial variability of the property. Karlen et al. (1997) proposed that soil quality can be evaluated at a wide range of scales, while Pennock et al. (1994) discussed scaling up data from discrete sampling points to landscape and regional scales.

One example of investigating spatial variability of soil quality is the study by Cambardella et al. (2004). They investigated the effect of topographic position on soil quality changes produced by different tillage practices in three small Iowa watersheds using terrain analysis methods. They found differences in soil properties used to assess soil quality among the different

landform elements and found differences in soil quality among the three experimental watersheds. In their analysis, soil erosion played a major role in reducing soil quality on steeper slopes in the three watersheds. Karlen et al. (2008)—also working at the watershed scale in Iowa—used a number of tools to examine soil quality and to consider differences in soil quality at different landscape positions. They found that a soil quality index (SQI) was helpful in assessing the potential for soil degradation and for making management decisions.

Sparling and Schipper (2002) evaluated soil quality as part of an environmental assessment on a national scale for New Zealand using 222 sites in five regions. As in many studies, only 10 cm of the surface were sampled and analyzed. The chemical, physical, and biological properties of the soil over 200 sites were measured and then statistically analyzed to determine the relationships between land use and soil quality indicators at this location. Variability was high, as might be expected for the range of soil types, landscapes, and land uses in the survey. This demonstrates some of the difficulty of extrapolating soil quality concepts from a pedon to larger spatial scales. It also indicates the value of evaluating the soil quality for a "whole soil," which means sampling throughout the profile and not just the top 10 cm.

26.3.2 Examples of Soil Quality Indicators

Soil quality is an attribute of a soil that is inferred from soil characteristics or indirect observations. To proceed from a definition to a measure of soil quality, an MDS of soil characteristics that represents soil quality must be selected and quantified (Larson and Pierce, 1991, 1994; Gregorich et al, 1994; Papendick et al., 1995; Karlen et al., 2001; Idowu et al., 2008; Rodrigues de Lima et al., 2008). The MDS may include biological, chemical, or physical soil characteristics (Table 26.4). For agriculture, the measurement of properties should lead to a relatively simple and accurate way to rank soils based on potential plant production without soil degradation or excessively adverse environmental effects. Unfortunately, commonly identified soil quality parameters may not correlate well with yield (Reganold, 1988).

Four points are relevant to the selection and quantification of soil characteristics: (1) soil characteristics may be desirable or undesirable, (2) soil renewability involves judgment of the extent to which soil characteristics can be controlled or managed, (3) rates of change in soil characteristics vary, and (4) there may be significant temporal or spatial variation in soil characteristics.

26.3.2.1 Physical Indicators

The physical characteristics of soil (Table 26.4) are a necessary part of soil quality assessment because they often cannot be easily improved (Karlen and Cambardella, 1996; Wagenet and Hutson, 1997; Idowu et al., 2008). Larson and Pierce (1991) summarized the physical indicators of soil quality as those properties that influence crop production by determining: (1) whether a soil can accommodate unobstructed root growth and provide

TABLE 26.4 Commonly Used Indicators of Soil Quality

Physical Indicators	Chemical Indicators	Biological Indicators
Aeration	Percent base saturation	Organic carbon content
Aggregates	Cation-exchange capacity and	Microbial biomass
Type (structure)	exchangeable acidity	Total
Stability		Bacterial
Size distribution		Fungal
Bulk density	Contaminants	Total C and N content ^a
	Types (Zn, Cu, Pb)	
	Availability	
	Concentrations	
	Mobility	
Clay mineralogy	Salinity (electrical conductivity)	Biomass C/total organic carbon
Color	Sodicity (ESP or SAR)	Potentially mineralizable N
Consistence (dry, moist, wet)	рН	Earthworm population
Thickness	Nutrients	Enzymes
Depth-to-root limiting layer	Content	Dehydrogenase
Profile thickness	Availability	Phosphatase
Surface layer thickness	Cycling rates	Arlysulfatase
Hydraulic conductivity	Total C and N content ^a	Nematode population

^a Carbon is sometimes considered a biological indicator, and a chemical indicator of soil quality.

pore space of sufficient size and continuity for root penetration and expansion, (2) the extent to which the soil matrix will resist deformation, and (3) the capacity of soil for water supply and aeration. Factors such as effective rooting depth, porosity or pore size distribution, bulk density, hydraulic conductivity, soil strength, and particle size distribution capture these soil functions. However, many of the processes that contribute to soil structure, aggregate stability, bulk density, and porosity are not well understood, making them difficult to manage. Proposed suites of physical parameters for soil quality evaluation are given in Letey (1985), Karlen et al. (1992), and Reganold and Palmer (1995). An example of regional and crop-dependent variation is evident

in the physical parameters proposed by Hulugalle and Scott (2008) for sustainable cotton growing in Australia.

Soil depth is a good example of an easily measured and independent property that provides direct information about a soil's ability to support plants. *Effective* soil depth is the depth available for roots to explore for water and nutrients. Effective soil depth is a problem for agricultural use of over 50% of soils in Africa (Eswaran et al., 1997). Soil depth requirements vary with crop or species. Many vegetable crops, for example, are notably shallow rooted while grain crops and some legumes, like alfalfa, are deep rooted. Variation will be even greater in unmanaged, natural systems. Wheat yield in Colorado was shown to decrease

from 2700 to 1150 kg ha⁻¹ over a 60 year period of cultivation primarily due to decrease in soil depth (Bowman et al., 1990).

Letey (1985) suggested that identification of a range of water content that is nonlimiting to plant productivity might be a good way of assessing the collective effect of soil's physical characteristics that contribute to crop productivity. For soils of decreasing quality, the width of the nonlimiting water range decreases. This and many of the physical parameters are highly variable over time and space (Moebius et al., 2007), thus making them difficult properties to assess when defining soil quality.

26.3.2.2 Chemical Indicators

Components of soil quality definitions may include desirable and undesirable chemical characteristics (Table 26.4). Desirable soil characteristics may either be the presence of a property that benefits soil productivity and/or other important soil functions, or the absence of a property that is detrimental to these functions. A soil characteristic may include a range of values that contributes positively to quality and a range that contributes negatively. Soil pH, for example, may be a positive or negative characteristic depending on its value. Larson and Pierce (1991) suggested that ranges of property values can be defined as optimal, suboptimal, or superoptimal. A pH range of 6–7.5 is optimal for the production of most crops, but the choice of optimal pH range can be crop dependent.

Undesirable soil characteristics may be either the presence of contaminants or a range of values of soil characteristics that contribute negatively to soil function. The presence of chemicals that inhibit plant root growth or the absence of nutrients that result in low yields or poor crop quality are examples of undesirable soil characteristics that lower soil quality.

Assessment of soil quality based on soil chemistry, whether the property is a contaminant or part of a healthy system, requires a sampling protocol, a method of chemical analysis, an understanding of how its chemistry affects biological systems and interacts with mineral forms, methods for location of possible contamination, and standards for soil characterization.

Nutrient availability depends on the physical and chemical processes of soil, such as weathering and buffering, and properties such as organic matter content, CEC, and pH. At low and high pH, for example, some nutrients become unavailable to plants and some toxic elements become more available. Larson and Pierce (1991) chose those chemical properties that either inhibit root growth or that affect nutrient supply due to the quantity present or the availability. Reganold and Palmer (1995) used chemical parameters related to nutrient availability as measures of soil quality, while Karlen et al. (1992) suggested that total and available plant nutrients and nutrient cycling rates should be included in soil quality assessments.

Soil properties may be severely compromised by intended or unintended human additions of chemical compounds, and soil productivity reduces if unwanted chemicals exceed safe thresholds. Data are required to determine whether a site is significantly polluted and if it requires cleanup (Beck et al., 1995; Sims et al., 1997). International standard methods have been created to

maintain the quality of measurements (Hortensius and Welling, 1996). A difficult determination is the level of each chemical that is considered an ecological risk. Beck et al. (1995) provided a list of levels for organic chemicals adopted by the Netherlands and Canada. Sims et al. (1997) argued that clean and unclean are two extremes of a continuum and that it is more appropriate to define the physical, chemical, and biological states of the soil as acceptable or unacceptable.

In the Netherlands, soil quality reference values have been created for heavy metals and organic chemicals based on a linear relationship with soil clay and organic matter content. The Dutch Ministry of Housing, Physical Planning, and Environment has used the maximum of a range of reference values for a given substance as a provisional reference value for good soil quality (de Bruijn and de Walle, 1988; Howard, 1993).

26.3.2.3 Biological Indicators

The focus of many soil quality definitions is soil biology, including microbial and biochemical soil properties (Table 26.4) (Filip, 2002; Schloter et al., 2003; Bending et al., 2004; Tian and Feng, 2008). Early work by Waksman (1927), who studied measurements of soil microorganisms that could indicate soil fertility, demonstrated that physical and chemical factors as well as soil biology were needed to predict soil fertility.

Soil microbiological properties are dynamic, highly responsive to management practices, and often difficult to measure or effectively evaluate. Soil quality evaluations have commonly included bulk measures of microbial activity such as microbial biomass, microbial respiration, and organic matter mineralization and denitrification (Karlen et al., 1992; Visser and Parkinson, 1992; Reganold et al., 1993; Franzluebbers et al., 1995; Yakovchenko et al., 1996; Boehn and Anderson, 1997; Franzluebbers and Arshad, 1997); or soil microbial C, phospholipid analyses, and soil enzymes (Franzluebbers et al., 1995; Jordan, et al., 1995; Gregorich et al., 1997).

Microbial communities are highly sensitive to changes in soil conditions (Kennedy and Papendick, 1995). Visser and Parkinson (1992) suggested evaluating microbiological criteria for soil quality at three levels; population, community, and ecosystem. Stork and Eggleton (1992) discussed species richness as a powerful but elusive indicator of invertebrate community and soil quality. Meso- and macrofauna populations have also been considered as part of soil quality evaluations (Berry, 1994; Reganold and Palmer, 1995; Hulugalle and Scott, 2008; van Eekeren et al., 2008).

More recently, Mele and Crowley (2008) investigated the use of statistical tools to make use of complex soil biology data sets. They noted that the biological properties of soil can range from single variables to complex multiparametric data sets, and reviewed an assortment of biological indicators and biological, structural, and functional indicators that have been used as soil quality parameters. They proposed the development of "ecologically derived algorithms that measure microbial community stability, richness, diversity, and functional redundancy resilience," acknowledging that this is an "outstanding challenge."

Total organic C and N are common, easily measured biochemical parameters in soil quality evaluations (Karlen et al., 1992; Franzluebbers et al., 1995; Franco-Vizcaíno, 1997; Gregorich et al., 1997; Sanchez et al., 2003). Measurement of one or more components of the N cycle including ammonification, nitrification, and nitrogen fixation may be used to assess soil fertility (Visser and Parkinson, 1992). Bending et al. (2004) argued that a wide variety of biochemical and microbial analyses should be used when comparing impacts of management on soil quality.

26.3.3 Approaches for Evaluating Soil Quality

Methods for evaluating soil quality are both qualitative and semiquantitative. Using more than one quantitative variable requires some system for combining the measurements into a useful index (Halvorson et al., 1996). This is one of the unmet challenges of creating a useful SQI. The region, crop, or general soil use for which an index was created will likely limit its effectiveness outside the scope of its intended application. Even an index designed only to rate productivity is not likely to be useful for all crops and soils, leading Gersmehl and Brown (1990) to advocate regionally targeted systems.

Rice is a good example of a crop requiring significantly different soil properties than other crops. It is a food staple for a large proportion of the world population. Approximately 146 million ha were in rice production in 1989 (FAO, 1989) mainly (90%) in Asia. High-quality soils for rice production may be poor quality for most other irrigated and dryland crops because they may be saline or sodic and high in clay with slow infiltration and permeability. These physical and chemical properties often constrain the production of other crops. Although they are not reviewed here, various land suitability classifications, specifically for rice, have been developed since the turn of the century (Dent, 1978).

Examples of several soil quality indexing systems are presented in the following sections. To some extent, recent attempts to enumerate the factors of soil quality resemble Jenny's (1941) introduction of the interrelated factors of soil formation.

26.3.3.1 Nonquantitative Evaluations

An index is categorized here as "nonquantitative" if it does not combine the evaluated parameters into a numerical index that rates soils along a continuous scale. Examples are the USDA Land Capability Classification (LCC) and the U.S. Bureau of Reclamation (USBR) Irrigation Suitability Classification.

The purpose of the Land Capability Classification is to place arable soils into groups based primarily on physical attributes affecting their ability to sustain common cultivated crops that do not require specialized site conditioning or treatment. Nonarable soils, unsuitable for long term, sustained cultivation are grouped according to their ability to support permanent vegetation and according to the risk of soil damage if mismanaged. Inherent fertility, organic matter, and other biological attributes are not evaluated. Several studies showed that lands of higher LCC have higher productivity than lands of lower LCC (Patterson and MacIntosh, 1976; van Vliet et al., 1979; Reganold and Singer, 1984).

The USBR Irrigation Suitability was a frequently used system of land evaluation for irrigation in the western United States during the period of rapid expansion of water delivery systems (USBR, 1953; Maletic and Hutchings, 1967; FAO, 1979; McRae and Burnham, 1981). As the area of irrigated agriculture continues to rise (Tilman et al., 2002; Pretty, 2008), and with potentially increasing water scarcity due to rising global temperatures (IPCC, 2007), the fundamental assessment of soil irrigability and management outcomes for water resources will continue to be relevant for soil quality assessment.

An emerging critique of older soil rating systems is that the true costs were not comprehensively evaluated (Robertson and Swinton, 2005). For example, the high energy and carbon inputs required to industrially produce inorganic N fertilizers using fossil fuels and the pollution effects of inefficient and excessive fertilizer application were not included in an economic analysis of management choices.

26.3.3.2 Quantitative Evaluations

We use "quantitative" to refer to systems that result in a numerical index or a descriptive category indicating quantitative assessment of key attributes. Indexing systems may be additive, multiplicative or have more complex functions. They have two important advantages over nonquantitative systems: (1) they are easier to use with GIS and other automated data retrieval and display systems, and (2) they typically provide a continuous scale of assessment. No single national system is presently in use, but several state or regional systems exist. Not all quantitative systems have functional relationships between indices and productivity. Some simply result in a numerical score that is easier to manipulate than nonnumerical rating systems.

Soil quality indices attempt to connect the multiple soil functions identified by soil quality definitions with intrinsic or quantifiable properties of soils as a means of evaluating the sustainability of management practices over time (Karlen et al., 2001; Table 26.5). Two criticisms of this approach have been that broad definitions of soil quality lead to simplistic soil indexing approaches, and that a better approach would simply evaluate individual functions using established metrics for, for example, productivity or susceptibility to erosion (Sojka et al., 2003). A second criticism is that the cost of collecting data to evaluate the complex multiple functions of soil makes such soil quality definitions impractical (Sanchez et al., 2003).

Compilation of an SQI requires an MDS of critical soil properties that are generally specific to a region and a particular land use. Examples of MDS can be found in Larson and Pierce (1991), Lilburne et al. (2002), Sparling and Schipper (2002), Rodrigues de Lima et al. (2008), and Villamil et al. (2008). Pedotransfer functions (Bouma, 1989a, 1989b) can be used to evaluate soil properties that are difficult to measure (Palm et al., 2007). Research on soil quality under different land uses and in different parts of the world has resulted in specific MDSs useful in defining and interpreting soil quality. Target values identify the magnitude of change constituting a significant effect on soil quality (e.g., Lilburne et al., 2002).

Evaluation for sustainable land management in the developing world. International Board for Soil Research and Management, Bangkok, Thailand. With Permission from the International Board for Soil Research and Management.

The Storie Index rating (SIR) is an early example of a numerical index of potential soil productivity. Although Storie considered the productivity of the land to be dependent on 32 soil, climate, and vegetative properties (Table 26.6), only nine properties were used in the SIR, because incorporating a greater number of factors made the system unwieldy. The nine factors, rated from 1% to 100%, are soil morphology (A), surface texture (B), slope (C), and six variables (Xi) that rate drainage class, sodicity, acidity, erosion, micro-relief, and fertility. The percentages are converted to their decimal value and multiplied together (Storie, 1932, 1964; Wier and Storie, 1936) (Equation 26.1):

SIR =
$$\left(A \times B \times C \times \sum_{i=1}^{6} X_i\right) \times 100$$
 (26.1)

Values for each factor were derived from Storie's experience of mapping and evaluating soils in California, and in soil productivity studies in cooperation with California Agricultural Experiment Station cost-efficiency projects relating to orchard crops, grapes, and cotton. In describing the SIR, Storie (1932, 1964) explicitly mentioned "soil quality." Soils that were deep had no restricting subsoil horizons, and held water well had the greatest potential for the widest range of crops. O'Geen et al. (2008) modified the Storie Index using modern mathematical techniques such as fuzzy logic to make the system less "operator dependent" and more useful with digital soils information.

The productivity index model (PI) was developed to evaluate soil productivity in the top 100 cm, especially with reference to potential productivity loss due to soil erosion (Neill, 1979; Kiniry, et al., 1983; Pierce et al., 1983). The PI model rates soils on the sufficiency for root growth based on potential available water storage capacity, bulk density, aeration, pH, and electrical conductivity. A value from zero to one is assigned to each property describing the importance of that parameter for root development. The product of these five index values is used to describe the fractional sufficiency of any soil layer for root development.

Pierce et al. (1983) modified the PI to include the assumption that nutrients were not limiting and that climate, management, and plant differences are constant. A number of authors found that it is useful to various degrees (Pierce et al., 1984; Gantzer and McCarty, 1987; Lindstrom et al., 1992).

Parr et al. (1992) suggested that an SQI could take the following form:

$$SQI = f(SP, P, E, H, ER, BD, FQ, MI)$$
 (26.2)

where SQI is a function of soil properties (SPs), potential productivity (P), environmental factors (E), human and animal health (H), erodibility (ER), biological diversity (BD), food quality and safety (FQ), and management inputs (MI). Determination of the specific measurable indicators of each variable and the interactions among these diverse variables is a daunting task. Moreover, the mathematical method of combining these factors, as well as the resulting value that would indicate a high-quality

soil, is not specified. The inclusion of variables BD, FQ, and MI makes this a land quality index as suggested by FAO (1997), and also raises issues of the scale of analysis for soil quality assessment. However, this holistic approach is similar to that of the Millennium Ecosystem Assessment (MEA, 2005), and it has been argued that this kind of approach is critical for the useful evaluation of soil management practices globally (Palm et al., 2007).

Larson and Pierce (1991) defined soil quality (Q) as the state of existence of soil relative to a standard or in terms of a degree of excellence. Q is defined as the sum of individual soil qualities qi and is expressed as

$$Q = f(q_i \dots q_n) \tag{26.3}$$

These authors did not identify the best subset of properties or their functional and quantitative relationship, but suggested that an MDS should be selected from those soil characteristics in which changes are measurable and relatively rapid (i.e., "dynamic" properties), arguing that it is more important to know about changes in soil quality (dQ) than the magnitude of Q (Larson and Pierce, 1991). Changes in soil quality are a function of changes in soil characteristics (q_i) over time (t):

$$dQ = f [(q_{i,t} - q_{i,t0})...(q_{n,t} - q_{n,t0})]$$
 (26.4)

If dQ/dt is ≥ 0 , the soil or ecosystem is improving relative to the standard at time t_0 . If dQ/dt < 0, soil degradation is occurring. Time zero can be selected to meet management needs or goals. If there is a drastic change in management, time zero can be defined as prior to the change. If a longer time period of comparison is considered more appropriate, properties of an uncultivated or pristine soil could be used.

Karlen et al. (1994) developed their SQI based on a 10 year crop residue management study. This SQI is based on four soil functions: (1) accommodating water entry, (2) retaining and supplying water to plants, (3) resisting degradation, and (4) supporting plant growth. Numerous properties were measured and values normalized based on standard scoring functions. Priorities were then assigned to each value. For example, aggregate stability was given the highest weight among factors important in water entry. After normalizing, each value is then multiplied by its weighting factor (wt) and products are summed

$$SQI = q_{we}(wt) + q_{wt}(wt) + q_{rd}(wt) + q_{spg}(wt)$$
 (26.5)

Subscripts refer to the four main functions described earlier. It should also be noted that resisting degradation (rd) and sustaining plant growth (spg) are assigned secondary and tertiary levels of properties that are themselves normalized and weighted before a final value is calculated and incorporated into Equation 26.5.

The resulting index resulted in values between 0 and 1. Of the three systems in the study, the one with the highest rate of organic matter return to the soil had the highest index value, and the soil with the lowest had the lowest value. The authors suggested that this demonstrates the usefulness of the index for monitoring the status and change in status of a soil as a function of management. They also suggested that the index and the soil characteristics that go into the index might change as the index is refined (Karlen et al., 1994).

Andrews et al. (2004) took the Karlen model a step further by creating a framework for incorporating multiple variables into an index. They recognized explicitly that soil quality varied depending on how a soil is to be used. They defined the indicators of soil quality as "those properties and processes that have greatest sensitivity to changes in soil function." They created a "Soil Management Assessment Framework (SMAF)" that utilizes a three-step framework of indicator selection, indicator interpretation, and integration into an SQI value. The database includes 81 indicators and 169 selection rules that allow the user to combine a soil management goal with supporting soil function into an SQI. Indicators have scoring curves that relate to concepts such as more of a property is better or less of a property is better. An example of a more is better curve includes total organic carbon and water stable aggregation (Andrews et al., 2004). An example

of a less is better curve is for bulk density. A single SQI score is then calculated as an average of the indicator scores.

As an example of the use of the SQI, Sharma et al. (2008) computed an SQI for sorghum (Sorghum bicolor (L.) Moench)mung bean (Vigna radiata L.) using key soil quality indicators. Twenty-one physical, chemical, and biological soil properties were measured and statistically treated to determine the MDS necessary to calculate the SQI. For the Alfisols being studied, they found that the available N, Zn, and Cu, microbial biomass carbon, aggregate mean weight diameter, and hydraulic conductivity were the variables most closely related to yield. Weighting factors were developed for each indicator, and these were used to calculate the SQI for different treatments on the soil. One finding was that tillage alone did not have a significant effect on the calculated SQI. Other researchers have also tested the SQI with varying results (e.g., Erkossa et al., 2007; Zobeck et al., 2008).

Smith et al. (1993) and Halvorson et al. (1996) proposed a multiple-variable indicator transform procedure to combine values or ranges of values that represent the best estimate of soil quality. Their system converts measured data values into a single value according to specified criteria. They did not attempt to define soil quality or specify what soil characteristics should be used. They combined this procedure with kriging to develop maps that indicated the probabilities of meeting a soil quality criterion on a land-scape level. Critical threshold values must be known, assumed, or determined in order to separate different soil qualities.

Numerous additive productivity rating systems have been developed for specific states, as reviewed by Huddleston (1984). In these systems, soil properties are assigned numerical values according to their expected impact on plant growth. The index is usually calculated as the sum of the values assigned to each property with 100 the maximum value. Huddleston (1984) notes advantages and disadvantages to such a system, which are similar to those for many of the soil quality indices previously discussed. Additive systems become complex as the number of factors, cropping systems, and soil and climatic conditions increases (e.g., Andrews et al., 2004; Velasquez et al., 2007). Other numerical systems have been proposed (Zornoza et al., 2007; Masto et al., 2008), using sophisticated statistics to develop relationships between the land use of interest and the MDS.

The evaluation of land quality for forestry is a well-known practice. Indices range from quantitative through semiquantitative to qualitative. Quantitative evaluations, such as the *site index*, use regression equations to predict tree height at a predetermined tree age based on soil and climate data. Qualitative evaluations assign land to classes based on soil and climate properties.

The Fertility Capability Classification (FCC) was developed in the early 1970s to interpret soil taxonomy and additional soil attributes in terms of their relevance to plant growth (Sanchez et al., 2003). Sanchez et al. (2003) argue for the use of an updated version of the FCC for a quantitative assessment of soil quality in the tropics. Table 26.7

(Palm et al., 2007) quantifies FCC attributes and constraints globally by latitudinal belts.

Palm et al. (2007) offer a re-evaluation of the soil quality debate that incorporates both an inventory of global soils and an evaluation of their current condition. They argue that "the natural capital of soils that underlies ecosystem services is primarily determined by three core soil properties: texture, mineralogy, and soil organic matter." They emphasize connections between soil types and biomes globally, and attempt to link specific soil processes, properties, constraints, and attributes with ecosystem services (Table 26.1) and quantify attributes and constraints globally (Table 26.7). They propose global mapping of soil properties in conjunction with the assessment of soil functions (Figure 26.7) (Palm et al., 2007). Subsequently, Sanchez et al. (2009) have argued that an ongoing effort to map soil properties globally and evaluate the condition of soils in conjunction with management recommendations for preventing soil degradation is critical for the protection of ecosystem services that rely on soil quality (Palm et al., 2007; Sanchez et al., 2009).

26.4 Conclusions

Soil quality is a concept developed to characterize the usefulness and health of soils because soils are fundamental to the well-being and productivity of agricultural and natural ecosystems. It is a compound characteristic that cannot be directly measured. Many definitions of soil quality can be found in the literature. Regional variation in soil properties and management ensures that no single set of soil characteristics can be universally adopted to quantify these definitions. Soil quality is often equated with agricultural productivity and sustainability, and is most commonly defined as a soil's potential to perform ecological functions in a system, for example, to maintain biological productivity, partition and regulate water and solute flow

through an ecosystem, serve as an environmental buffer, sequester carbon and cycle nutrients, water, and energy through the biosphere. Air and water quality standards are usually based on maximum allowable concentrations of materials hazardous to human health. A definition of soil quality based on this concept would encompass only a fraction of the important roles soils play in agriculture and the environment.

To proceed from a definition to a measure of soil quality, an MDS of soil characteristics that relate to soil functions is commonly selected and quantified. Many physical, chemical, and biological properties of soil have been suggested to distinguish soils of different qualities. These include desirable and undesirable properties. In selecting characteristics, it is necessary to recognize that some soil properties are static—in the sense that they change slowly over time—and others are dynamic. In addition, the spatial and temporal variability of soil properties must be considered when selecting the properties used to assess soil quality. Numerous approaches to soil quality assessment have been proposed. Recent efforts to inventory the global state and function of soils provide a useful reassessment of soil quality in the broader context of the intimate connection between global ecosystem health and human and societal well-being.

We face a profound challenge in evaluating and sustaining the broader ecological services that soils can provide with proper management, while still maintaining sufficient food and energy production for a population projected to reach 9 billion by 2050 (Tilman et al., 2002; Robertson and Swinton, 2005; Rockstrom et al., 2009a, 2009b), in the context of a changing climate likely to affect food production and ecosystem health in the near future (IPCC, 2007). Soil science research has helped to demonstrate that soils regulate global climate, food production, and ecological services critical to human survival. Our future now depends on our ability to effectively reform agricultural and other land use policies for vastly more effective management of soil resources.

IV-2 Soil Databases

Terrestrial Ecosystem of Planet Earth

For many years, soil scientists have addressed the question of the carrying capacity of the Earth. During the past 150 years crop and soil scientists have made extensive advances in increasing yields of crops and animal products to feed rapidly increasing populations. During more recent decades, environmental scientists have given increasing attention to the issue of sustainability of the Earth's terrestrial ecosystems, especially those ecosystems that are occupied and managed by human populations.

Within the last half century, remarkable advances have been made in several strategic technologies of importance to soil and other terrestrial ecosystem scientists. These include the computer, electronic digital information systems, and polar-orbiting Earth observation satellites with a wide array of digital sensors, including the digital camera. In addition to these new measuring devices, advanced digital analysis systems, and storage media for almost limitless quantities of data, two other remarkable developments have occurred. One is the U.S. military declassification in the 1990s of Global Positioning Systems (GPS) data for use by the civilian community. This means that any soil scientist (or anyone else) with rather inexpensive equipment can locate a site anywhere on the Earth surface within an accuracy of a fraction of a meter. A second development is the capacity to transmit and share large volumes of digital data instantaneously from one address on the Earth surface to potentially any other address on the Earth surface.

Role of Soil Databases in Understanding and Managing Terrestrial Ecosystems

Selected soil science colleagues from around the world were invited to participate in the development of Part IV of this handbook. The authors were invited to prepare manuscripts that provide a current view of the soil databases of their country, region, or the world. This description of their soil databases was to be

followed by a discussion of how the new information technologies are being used by the soil science community to make soil data and information available to the User Community. This User Community is defined to include agricultural producers, foresters, private industries, government agencies, and any others who have responsibilities in the use and management of terrestrial ecosystems anywhere.

Part IV includes seven chapters on soil databases. In Chapter 27, Nachtergaele, FAO, Rome, and colleagues present "Qualitative and Quantitative Aspects of World and Regional Soil Databases and Maps." Chapters 28 through 31 describe the development and use of national and state soil databases in four of the world's largest agricultural and timber producers— Brazil, China, Russia, and the United States. A study of these four large and complex soil databases from three continents suggests the need for information systems which may assist in bridging the gaps among the inconsistencies and incompatibilities of different soil classification systems. Chapter 32 by Paterson and Mushia from South Africa presents an overview of the database situation for the continent of Africa while in Chapter 33, D.G. Schulze and colleagues, Purdue University, West Lafayette, Indiana, complete this part with their presentation on "Learning about soil resources with digital soil maps." Their illustrations provide an idea of the almost unlimited possibilities for distributing useful and understandable soils information to anyone in the world involved in the management and conservation of terrestrial ecosystems.

Many other countries, regions, and organizations have activities related to the development of soil databases. Two other areas of the world where significant progress is being made in the development of soil databases are Europe and Africa. The effort to produce an integrated soil database for Europe is well along in its complex task. The creation and development of a useful and compatible soil database to meet the needs of the newly developing Alliance for Green Revolution in Africa (AGRA) are in the initial stages.

27.1 Introduction

Soil databases take various forms and have evolved quite rapidly recently. About 20 years ago, most soil data were produced as paper soil maps accompanied by a soil survey report, which usually contained thick annexes with soil profile descriptions and laboratory data. Nowadays, however, soil information is most likely to come stored in a Geographical Information System (GIS) accompanied by a digital database containing the soil profile information linked as point data to the corresponding soil mapping unit polygon. The data sets are stored in various media ranging from stand-alone media like CD-ROMs to globally accessible Internet GIS servers. Queries can vary as well: from locally operated GIS software for the fully trained GIS operators toward full internet GIS server functionality for nonspecialists.

While this technological revolution is in no way a guarantee for an enhanced quality of the data itself, it has assured that presentation of soil data has become more accessible to potential users and decision makers. This is true regardless of the geographic location, as computers and GIS software are nowadays to be found in all but the most remote places. Fast Internet access, on the other hand, still remains largely limited to the developed world, although developing countries are fast catching up.

Soil survey is at a crossroad. Over the last several years, pessimistic views have been expressed about its future. Some of the reasons put forward are external to soil survey and are strongly influenced by the general economic situation. Inappropriate presentation and the poor accuracy of soil information, together with high survey costs, are often to blame. The worldwide crisis

in collecting primary field data in general may also partly be blamed by the overreliance on the use of satellite imagery as the ideal tool to carry out natural resources inventories. Although satellite imagery is an extremely useful tool to assist surveys, even at the highest resolution it limits observation mainly to surface features like land cover. The actual land use and underlying soil layers are largely undetectable to even the high resolution sensors of recent satellites, although a number of soil properties can now be detected with a certain degree of confidence (Hartemink et al., 2008).

Another factor responsible for this field data crisis is political and is particularly true for the collection of soil data in Western Europe where most national soil survey institutes have closed down or were privatized and have all abandoned systematic soil mapping. This is particularly critical for a region that with few exceptions (Belgium, Denmark, the Netherlands, United Kingdom) had a scant and insufficient soil information system before privatization, compared to say, Eastern Europe and the United States.

The situation in tropical countries, or in the developing world in general, is more varied in this respect, as overall there are still relatively strong soil institutes in most countries backed by, albeit insufficient, government funds. Systematic surveys are limited but still continue in most countries and have resulted in national maps and databases that with regard to detail of scale and number of available soil profiles can easily compete with those of countries in the industrialized world. Curiously, the so-called recession in carrying out soil surveys thus appears to have affected developing countries less than developed ones

(Hodgson, 1991). However, when data concerning the European Community (Lee, 1991) are compared to those of the less advanced countries (Zinck, 1990), the differences in soil survey status are less than might be initially expected. This is because there is renewed interest at the EC level as a whole (the EU Soil Thematic Strategy, the Soil Protection law in Germany, new national soil mapping program in Italy). Nowadays, inequalities between developing and developed countries appear to be deepening rather than shrinking.

A last introductory remark concerns the problem of information access, which is not unique for soil data but applies for many other natural resources data (climate, geology, etc.) as well. The problem appears most acute in Europe, but recent developments point to an increase of data access problem in Africa and Asia as well.

In Europe, several phenomena have accelerated data access problems. The first event was the privatization process that started in the late 1970s and resulted in national soil institutes being no longer subsidized as was the case in the past. The only valuable money source present in these institutes, apart from human resources, appeared to be the data and maps that had been compiled over the years. These were consequently marketed and commercialized and seen as an extra source of income. Strict copyright rules were put in place to avoid misuse and illegal reproduction of the data.

Another, less well-documented phenomenon causing data access problems appears to be the accelerated regionalization within the EU in which the power of some regions within countries (particularly in Germany, but also in Italy, France, and Belgium) have become much more expressed. These countries have legally limited the data access that national institutes are allowed to extend to interested researchers or commercial companies. As international organizations can only discuss data availability with national entities, the problem becomes more difficult to solve.

The approach of UN agencies such as the Food and Agriculture Organization (FAO) is that data should be made available at their production and maintenance costs only.

27.2 Global Soil Maps and Databases

27.2.1 The FAO-UNESCO Soil Map of the World

At the global level, the 1:5 M scale *Soil Map of the World* (FAO-UNESCO, 1971–1981) was until recently, nearly 30 years after its finalization, the only worldwide, consistent, harmonized soil inventory that was readily available in digital format and came with a set of estimated soil properties for each mapping unit.

The *Soil Map of the World* project originated by a motion of the International Society of Soil Science (ISSS) at the Wisconsin congress in 1960, started in 1961 and was completed over a span of 20 years. The first draft of the *Soil Map of the World* was presented to the Ninth Congress of the ISSS, in Adelaide, Australia, in 1968. The first sheets, those covering South America, were

issued in 1971. The last and final map sheet for Europe appeared in 1981 (FAO-UNESCO, 1971–1981).

With the rapidly advancing computer technology and the expansion of GISs during the 1980s, the *Soil Map of the World* was first digitized by ESRI (1984) in vector format. Subsequently, a first rasterized version of the soil map was prepared by Zobler (1986) using the ESRI map as a base and using 1×1 grid cells. Only the dominant FAO soil unit in each cell was indicated; this digital product gained popularity because of its simplicity and ease of use, particularly in the United States, but should no longer be used.

FAO (1995a) produced its own raster version that had the finest resolution with a 5′ × 5′ cell size (9 km × 9 km at the equator) and contained a full database corresponding with the information in the paper map in terms of composition of the soil units, topsoil texture, slope class, and soil phase in each of the more than 5000 mapping units. In addition to the vector and raster maps discussed above, the CD-ROM contains a large number of databases and digital maps based on statistically derived soil properties (pH, organic carbon, C/N, soil moisture storage capacity, soil depth, etc.) for predefined depth zones (0–30 and 30–100 cm). The CD-ROM also contains interpretation by country on the extent of specific problem soils, the fertility capability classification results by country, and corresponding maps (FAO and IIASA, 2002).

27.2.2 The Harmonized World Soil Database

Recognizing the urgent need for improved soil information worldwide, particularly in the context of the Climate Change Convention and the Kyoto Protocol for soil carbon measurements and the immediate requirement for the update of the FAO/International Institute for Applied Systems Analysis (IIASA) Global Agro-ecological Assessment study (FAO-IIASA, 2002), the FAO of the United Nations and the IIASA took the initiative of combining the recently collected vast volumes of regional and national updates of soil information with the information already contained within the 1:5,000,000 scale FAO-UNESCO Digital *Soil Map of the World* into a new comprehensive Harmonized World Soil Database (HWSD; FAO/IIASA/ISRIC/ISSCAS/JRC, 2008).

This state-of-the-art database was achieved in partnership with

- The International Soil Reference and Information Centre (ISRIC-World Soil Information) together with FAO, responsible for the development of regional soil and terrain databases (SOTER, see Section 27.3) and the ISRIC-WISE soil profile database (see Section 27.4)
- The European Soil Bureau Network (ESBN), which had recently completed a major update of soil information for Europe and northern Eurasia
- The Institute of Soil Science, Chinese Academy of Sciences that provided the recent 1:1,000,000 scale soil map of China

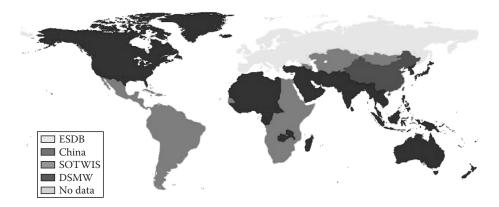

FIGURE 27.1 Source material for the Harmonized World Soil Database. (ESDB: European Soil Database; China: Soil Map of China 1:1 M; SOTWIS: secondary databases derived from SOTER and WISE; DSMW: Digital Soil Map of the World.)

In order to estimate soil properties in a harmonized way, the use of actual soil profile data and the development of pedo-transfer rules were undertaken in cooperation with ISRIC and ESBN drawing on the ISRIC-WISE soil profile database and the earlier work of Van Ranst et al. (1995), Batjes et al. (1997, 2007), and Batjes (2002).

The harmonization and data entry in a GIS was assured at IIASA and verification of the database was undertaken by all partners. As the main aim of the product is to be of practical use to modelers and to serve perspective studies in agro-ecological zoning, food security, and climate change impacts (among others), a resolution of about $1\,\mathrm{km}$ (30 as \times 30 as) was selected. Over 15,000 different soil mapping units are recognized in the HWSD; source materials are shown in Figure 27.1.

The resulting raster database consists of 21,600 rows and 43,200 columns, which are linked to harmonized attribute data.

The use of a standardized structure allows linkage of the attribute data with GIS to display or query the map unit composition in terms of soil units and the characterization of selected soil parameters (organic carbon, pH, soil moisture storage capacity, soil depth, cation exchange capacity of the soil and the clay fraction, total exchangeable nutrients, lime and gypsum contents, sodium exchange percentage, salinity, textural class, and granulometry) that can be used in a wide range of environmental assessments at global level. Soil reaction (pH), for example (Figure 27.2), provides a measure for the solubility of various compounds in a soil, the relative bonding of nutrient ions to exchange sites, and the activity of various microorganisms.

The HWSD map, database, and a viewer are available on CD-ROM and freely downloadable from FAO/IIASA/ISRIC/ISSCAS/JRC (2008).

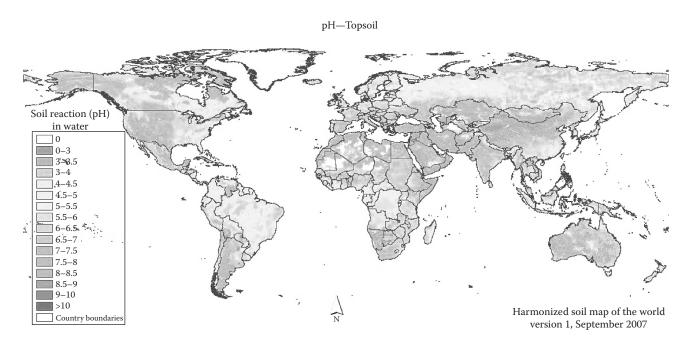

FIGURE 27.2 Global distribution of soil reaction (pH; 0–30 cm) according to HWSD.

Reliability of the information presented on the HWSD is variable: the parts of the database that still make use of the *Soil Map of the World* such as North America, Australia, West Africa, and South Asia are considered less reliable, while most of the areas covered by SOTER databases are considered to have the highest reliability (Southern Africa, Latin America and the Caribbean, Central and Eastern Europe).

Further expansion and update of the HWSD is foreseen for the near future, notably with the information held in the U.S. Natural Resources Conservation Service's U.S. General Soils Map (STATSGO, 2009), the Canadian Soil Database (Agriculture and Agrifood Canada, 2009), and the soil database for Australia (CSIRO/ACLEP, 2009).

27.3 Regional Soil and Terrain Databases (SOTER)

The discussion paper "Towards a Global Soil Resources Inventory at Scale 1:1 Million" (Sombroek, 1984) was an initiator for an ISSS (now International Union of Soil Sciences—IUSS) program to update and expand the global spatial soil information. In 1987, the idea was further elaborated and resulted in the development of the SOTER methodology (FAO, 1995b; Van Engelen and Wen, 1995).

FAO recognized that a rapid update of the *Soil Map of the World* would be a feasible option if the original map scale of 1:5 M was retained, and started, together with the United Nations Environment Programme (UNEP) and ISRIC, to fund

national updates at a 1:5 M scale of soil maps in Latin America and Northern Asia following the standardized SOTER approach. These parallel programs of ISRIC, UNEP, and FAO merged together in mid-1995, when the three major partners agreed to join the concerned resources and work toward a common world SOTER approach covering the globe at a 1:1 M scale. Since then, other international organizations have shown support and collaborated to develop SOTER databases for specific regions. This is, for instance, the case for Northern and Central Eurasia, where IIASA joined FAO and the national institutes involved (FAO and IIASA, 1999).

Basic in the SOTER approach is the mapping of tracts of land (SOTER units) with a distinctive, often repetitive, pattern of landform, soil parent material, surface form, slope, and soil (Van Engelen and Wen, 1995). Each SOTER unit represents a unique combination of terrain and soil characteristics; Figure 27.3 shows how the terrain and soils are represented by a SOTER unit in the database.

It should be noted that although the information is collected according to the same SOTER methodology, the specific level of information in each region results in a variable scale of the end products presented. The soils and terrain database for northeastern Africa (FAO et al., 1998a), for instance, contains information at equivalent scales between 1:1 and 1:2 M, but the soil profile information is not geo-referenced. For north and central Eurasia, profile information is very limited (FAO and IIASA, 1999). Fully comprehensive information is available for the SOTER database of South and Central America and the Caribbean (FAO et al., 1998b; Dijkshoorn et al., 2005) and includes more than 1800

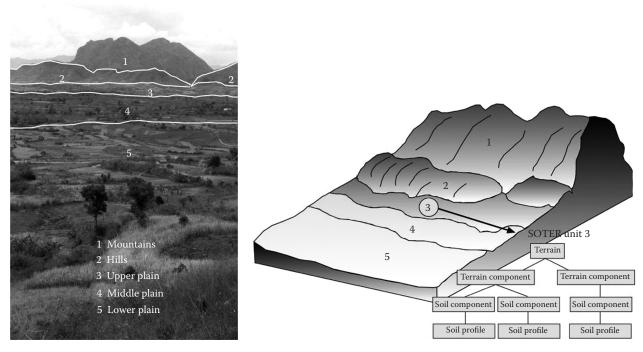

FIGURE 27.3 Terrain and soils in the SOTER database.

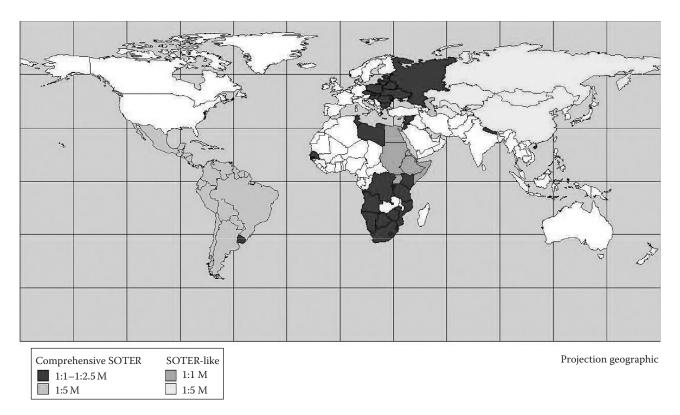

FIGURE 27.4 World SOTER status in 2009.

geo-referenced soil profiles. The SOTER database for Central and Eastern Europe (1:2.5 M scale) contains over 600 geo-referenced soil profiles (FAO and ISRIC, 2000). The scales of the SOTER database of Southern Africa (FAO and ISRIC, 2003) and of Central Africa (FAO et al., 2007) range between 1:1 M for most countries and 1:2 M for Angola and the Democratic Republic of the Congo.

The current world coverage by SOTER is given in Figure 27.4; comprehensive SOTER databases are developed according to the methodology described by Van Engelen and Wen (1995). Conversely, SOTER-like databases characterize the soil and terrain conditions but they do not contain any measured soil profile data.

Soil analytical data held in comprehensive SOTER have been analyzed according to a range of methods and in various laboratories, and these are documented in the various data sets. Generally, however, there are many gaps in the measured soil analytical data stored in primary SOTER databases—typically, not all the attributes that can be handled in SOTER have been collected during the ground surveys that provided the legacy profile data. Such gaps in the attribute data will often preclude the direct use of primary SOTER databases for modeling.

For practical reasons, a distinction is therefore made between (1) primary SOTER databases that provide full information on terrain unit composition in terms of landform, parent materials, as well as a suite of geo-referenced soil profile data with inherent gaps in the soil analytical data, and (2) *secondary* or *SOTWIS* databases in which gaps in the measured profile data have been

filled using consistent taxotransfer procedures for selected soil attributes thus facilitating modeling; for details see Section 27.4. Both types of databases may be downloaded through the ISRIC web site (www.isric.org) using the "soil data on-line" button.

An update of the SOTER methodology started in 2008 within e-SOTER, an EU Seventh Framework Program financed research project with 14 partners from Europe, Morocco, and China. The project addresses four major barriers to a comprehensive soil observing system:

- Morphometric descriptions—enabling quantitative mapping of landforms (Dobos et al., 2005) as opposed to crude slope categories as well as newly developed DEM analysis using natural breaks
- Soil parent material characterization and pattern recognition by remote sensing and using legacy data will enable a separation of soil processes within the landscape and will generate a parent material classification relevant for soil development
- Soil pattern recognition by remote sensing will generate additional predictors of soil properties
- Standardization of methods and measures of soil attributes to convert legacy data already held in the European Geographical Soil Database and various national databases to a common standard so that they may be applied, for example, in predictive and descriptive models of soil behavior

27.4 ISRIC-WISE Harmonized Global Soil Profile Database

In the early 1990s, staff at ISRIC developed a uniform methodology for a global soil database in the framework of a project entitled "World Inventory of Soil Emission Potentials" (ISRIC-WISE). WISE was especially conceived for a geographical quantification of main soil factors that control processes of global change on a broad scale (Batjes and Bridges, 1994; Batjes et al., 1995).

Profiles in WISE have been classified according to the original and the revised Legend of the *Soil Map of the World* (FAO-Unesco, 1974; FAO, 1988). Thereby, interpretations derived from primary (measured) data held in WISE can be linked to the spatial units of both digitized and digital soil maps that use either of these Legends (e.g., Batjes, 2002; Batjes et al., 2007; FAO/IIASA/ISRIC/ISSCAS/JRC, 2008).

In the process of collating materials for compilation of the ISRIC-WISE profile database, the quality and validity of the original data had to be evaluated carefully, while at the same time recognizing that these are the only materials available. The description status of the various profiles has been documented in WISE to provide a coarse indicator for the inferred reliability of the source data (Table 27.1); typically, status four (low) profiles are purged from WISE when better data become available for the corresponding soil units.

The latest public domain release of WISE, version 3.1, comprises data for some 10,250 profiles with some 47,800 horizons, from 149 countries (Batjes, 2008, 2009), as opposed to some 4,350 profiles in an earlier version (Batjes, 1999). Most profiles are from Africa (41%), followed by Asia (18%), South America (18%), and Europe (13%) (Table 27.1); their approximate location is shown in Figure 27.5.

TABLE 27.1 Number of Profiles in WISE3 by Continent and Their Description Status

	Pro	Profile Description Status ^a					
Continent	1	2	3	4	Total		
Africa	421	1337	2392	23	4173		
Asia	441	970	426	10	1847		
Antarctica	4	6	0	0	10		
Europe	225	712	359	20	1316		
North America	495	222	127	11	855		
Oceania	50	49	106	4	209		
South America	149	1380	313	1	1843		
Total	1785	4676	3723	69	10253		

Source: Batjes, N.H. 2009. Harmonized soil profile data for applications at global and continental scales: Updates to the WISE database. Soil Use Manage. 25:124–127.

^a The number code under *profile description status* refers to the completeness and apparent reliability of the soil profile descriptions and accompanying analytical data for the specified profile in the original source; the status is the highest for 1 and the lowest for 4 (see FAO, 2006). Continents are defined according to Times Atlas (2003).

Profile data in WISE3 originate from over 260 different sources, both analog and digital. Some 40% of the profiles were extracted from auxiliary datasets, including the ISRIC Soil Information System (ISIS), the NSSC Soil Survey Laboratory Soil Characterization Database (USDA-NRCS, 2008), various SOTER databases, and the FAO Soil Database (FAO-SDB).

Overall, chemical and physical analyses have taken place in at least 150 laboratories worldwide, using a range of methods; these are described in broad terms in WISE. Analytical methods used in ISIS and the NSSC collection may be considered to be similar (van Reeuwijk, 1983; Vogel, 1994). Conversely, for the other sources, methods typically vary from one laboratory to the next, even within one country, and may change over time within a single laboratory. These methodological differences complicate the worldwide comparison of soil analytical datano single solution for addressing this issue has been found as yet (Wilson, 1979; van Reeuwijk, 1983; Vogel, 1994; FAO, 1995a, 1995b; Batjes et al., 1997; Breuning-Madsen and Jones, 1998; Hollis et al., 2006; FAO/IIASA/ISRIC/ISSCAS/JRC, 2008). As a result, the amount of measured data available for modeling is sometimes much less than expected. Conversely, the issue of comparability of soil analytical data should always be considered in relation to the scale at which the derived data are to be used. Adroit use of the data stored in WISE will permit a wide range of agricultural and environmental applications at global and continental scales (1:500,000 and broader). Published examples of such applications include, the development of harmonized sets of derived soil properties for the main soil types of the world, gap-filling in primary SOTER databases using consistent pedotransfer procedures (resulting in so-called secondary SOTWIS databases), global modeling of environmental change, analyses of global ecosystems, upscaling and downscaling of greenhouse gas emissions, and crop simulation and agro-ecological zoning (see ISRIC-WISE, 2008).

An important application of large, harmonized profile data-bases such as WISE remains making other databases, such as primary SOTER sets, widely usable. Without supporting auxiliary soil profile data that permit thorough statistical analyses and the development of pedo-transfer procedures, such databases would remain fraught with numerous gaps in the measured data thereby precluding modeling applications. Further, by implication, this would preclude the expansion of derived soil products, such as the HWSD, that draw heavily on WISE-derived data. Large profile databases such as WISE are also needed for studying relationships in soil distribution and for providing soil legacy data for the Digital Soil Mapping project discussed in Section 27.5.

27.5 Digital Soil Mapping

In 2006, a consortium of scientific institutes, centers, and universities launched an appeal to use the latest satellite technology and new information layers, such as the recently

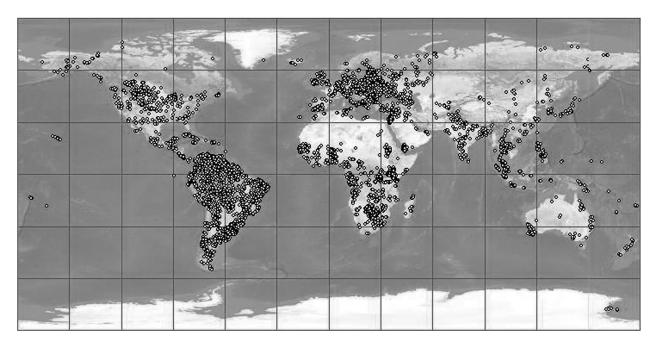

FIGURE 27.5 (See color insert.) Global distribution of geo-referenced soil profiles in WISE3. (From Batjes, N.H. 2008. ISRIC-WISE harmonized global soil profile dataset (Version 3.1). Report 2008/02. ISRIC—World Soil Information, Wageningen, the Netherlands. (http://www.isric.org/isric/webdocs/docs/ISRIC_Report_2008_02.pdf).

released topographic information at 90 m resolution, to achieve a spatial database of soil properties, based on a statistical sample of landscapes (see GlobalSoilMap.net, 2009). Within the sample or satellite sites, field sampling is used to determine the spatial distribution of soil properties in order to develop reflectance spectral libraries for characterization of soil properties (Shepherd and Walsh, 2002). These are then used to predict soil properties in areas not sampled, also using covariates reflecting state factors of soil formation; details may be found elsewhere (see McBratney et al., 2003; Lagacherie et al., 2006; Hartemink et al., 2008). The resulting digital soil maps describe the uncertainties associated with such predictions and, when based on time-series data, can also provide information on dynamic soil properties. Maps derived from digital soil mapping differ from conventional, polygon-based maps in that they are pixel-based and thus can be more easily displayed at a higher resolution than those currently used by other earth and social sciences (Sanchez et al., 2009).

The GlobalSoilMap.net (2009) project, funded by the Bill & Melinda Gates Foundation in 2008, started with a pilot covering sub-Saharan Africa (AfSIS). Regional nodes in other continents were also established.

As summarized by Sanchez et al. (2009), GlobalSoilMap. net proceeds in five steps with the ultimate aim to develop evidence-based soil management recommendations at very high resolution. The first three steps are relevant here as they concern the establishment of a digital soil map. The first step, Data Input, starts with the production of base maps that are

compiled from topography, climatic information, land cover, and geological variables relating to soil parent materials (using airborne gamma radiometric spectroscopy). Pre-existing georeferenced field and laboratory measurements, also known as conventional or soil legacy data, are needed at this stage (Carre et al., 2007). Secondly, soil properties are estimated using soil probability functions that express the probabilities of occurrence of a certain predictor value. During the initial stages, six soil properties will be considered: clay content, organic carbon content, pH, estimated cation-exchange capacity, electrical conductivity, and bulk density. These may be used to generate a range of maps as discussed by Sanchez et al. (2009). Finally, during the third step, spatially inferred soil properties are used to predict more difficult-to-measure soil functions such as available soil water storage, carbon density, and phosphorus fixation. This is achieved using pedo-transfer functions.

An innovative element of the approach is that the overall uncertainty of the prediction will be determined by combining uncertainties of the input data, a spatial inference model, and soil functions used.

Several pilot projects are underway to support the theories that underlie GlobalSoilMap.net of which work in Australia is probably the most advanced. Experimentation with various approaches is gradually leading toward consensus. Conversely, as with any new approach, a number of scientific and operational challenges still need to be resolved; these have been discussed in detail by various authors (see Lagacherie et al., 2006; Hartemink et al., 2008).

27.6 Conclusions and Recommendations

27.6.1 Conclusions

- Conventional soil survey and mapping have declined considerably in many areas of the globe, while at the same time the development of new technologies have favored the enhanced development of soil property databases and models to predict, at high resolution, certain soil characteristics of interest for agriculture or the environment.
- The most significant global and regional soil maps and databases are nowadays freely available and downloadable online. Conversely, national and subnational soil data access remains a problem or comes at a cost in many countries.
- 3. The main purpose of the FAO-UNESCO *Soil Map of the World* was to illustrate the geographical distribution of different major soil types globally. More recent regional efforts have focused on quantifying a selected number of soil properties for defined soil units. Soil classification remains an important element in these mapping approaches. Generally, the spatial and attribute uncertainty is still poorly quantified in these products and the spatial resolution remains coarse.
- 4. SOTER and HWSD are close to achieve satisfactory developing world coverage, except for South East Asia and West Africa, but are lacking recent information on the industrial world with the exception of Europe.
- 5. Soil profile databases such as WISE have had to overcome numerous problems of data access and the lack of harmonized soil analytical methods, but have reached a stage where impressive world coverage is achieved. Significant geographical areas (Central and Northern Eurasia, Deserts) still lack adequate soil data however.
- 6. The digital soil mapping project has just started with a pilot focusing on Africa. Once tested and validated, the resulting techniques will allow quantifying the overall uncertainty of the predictions by combining uncertainties of the input data, spatial inference model, and soil functions. Conversely, in these approaches, one may move away from understanding the soil distribution in a land-scape to a statistical representation of soil properties for soil management purposes.

27.6.2 Recommendations

 Policy makers should be made aware of the importance of good quality soil data to address major challenges facing the world be it climatic change mitigation, securing food security, or remedying water scarcity. The soil science community has a key role to play in this process—crosscorrelations between uncertain variables will determine how uncertainties will propagate in a modeling study, and accuracy levels considered to be acceptable will vary with the scale and type of questions being asked (Finke, 2006; Heuvelink and Brown, 2006).

- 2. Sufficient resources should be made available to complete the SOTER/HWSD approach with data from the industrial world and some of the other geographical areas still missing (notably West Africa and Southeast Asia). Ultimately, this information, complemented with WISE profile data for so far underrepresented regions, should be used to compile a world covering SOTER product.
- 3. In conjunction with the above, new digital soil mapping approaches, as currently being developed, tested, and validated for sub-Saharan Africa in the framework of GlobalSoilMap.net, should be expanded to the other continents.

28.1 Introduction

Soil surveys have been conducted in the United States since about 1886. An organized soil survey program began in 1899. In 1953, the Secretary of Agriculture established the National Cooperative Soil Survey (NCSS), a group of federal and state agencies and universities loosely knit through cooperative agreements, in part to accelerate the completion of soil surveys. The USDA Natural Resources Conservation Service (NRCS), formerly the Soil Conservation Service (SCS), provides federal leadership to the NCSS. Soil surveys and supporting pedagogical studies conducted through the NCSS are complete for about 91% of all lands in the United States and its territories. About 96% of the privately owned land has a detailed soil survey, generally at a scale of 1:12,000-1:24,000. Information about soils is available in approximately 3000 county-level soil survey reports and databases. A digital soil survey at a scale of 1:250,000 for the United States (1:1 million for Alaska) is also available. Each year, between 50 and 100 new soil surveys with digital spatial and attribute data and corresponding soil survey reports are developed and published. Most completed soil surveys have been digitized and are available online.

Beginning in the late 1960s and early 1970s, NCSS soil scientists recognized the need for and the potential utility of automating the large quantity of soil survey information that was being generated. In the more than 30 years since, the NCSS has been an innovative leader in the adaptation and use of information technology. As a result, the demand for soil survey information is greater than it has ever been. A National Soil Information System

(NASIS) was introduced in 1994 to improve the acquisition and management of these data. To improve the distribution of digital data, the Soil Data Mart (SDM) was implemented in 2003 and the Web Soil Survey (WSS) was implemented in 2005.

28.2 Description of Soil Survey Databases

The NRCS and NCSS develop and maintain six databases. These are the (1) Soil Characterization Database (SCD), (2) NASIS, (3) Official Series Descriptions (OSDs), (4) Soil Classification Database (SC), (5) Soil Survey Geographic Database (SSURGO), and (6) the U.S. General Soil Map (STATSGO). Each set of data was developed for a specific need or purpose. A simplified schema of how these data are related is presented in Figure 28.1. Information contained within these databases has been reviewed and certified in accordance with NCSS data-quality standards (Soil Survey Staff, 1995a, 2009).

28.2.1 Soil Characterization Database

This database stores the laboratory characterization of about 20,000 pedons from the United States and about 1,100 pedons from other countries. Soil profile descriptions are available for about 15,000 of these pedons. These data were produced primarily by the Soil Survey Laboratory (SSL) at the National Soil Survey Center (NSSC), Lincoln, Nebraska, and at previous SCS laboratories located in Beltsville, Maryland, and Riverside, California.

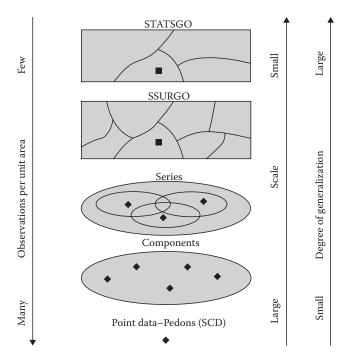

FIGURE 28.1 Spatial data relationships. (Modified from Waltman, 1997, personal communication.)

Sample preparation and analytical procedures are carried out according to standard methods (Soil Survey Staff, 1996). The NSSC has produced a guide for interpreting the information (Soil Survey Staff, 1995a). These pedons are sampled by NRCS scientists and NCSS cooperators at universities and at state and other federal agencies. Sites are usually selected to represent the concept of a soil series. Over time, as they are sampled and characterized, these pedons bracket a range of soil properties for a soil series or landscape. These data are used to populate the values for physical and chemical soil properties in the soil map unit data and OSDs and for research purposes, such as the development of environmental models.

Programming for the development of this database began at the SSL as early as 1966, when the calculation and reporting of bulk density, particle size, chemical, and mineralogical analysis were automated. These early efforts evolved into the development of a Laboratory Information Management System (LIMS) that collects, controls quality, calculates, and reports laboratory analysis results. As analytical data from sampling projects are completed, they are reviewed and verified. Data are then published in the Soil Characterization Database. These data are available via a public Web site at http://ssldata.nrcs.usda.gov/.

As part of the NCSS, many universities have developed SSL characterization data for the soil surveys in their respective states. Institutions with significant databases include the University of California at Davis, Clemson University, Colorado State University, University of Florida, Kansas State University, University of Idaho, University of Illinois, Louisiana State University, University of Maine, Michigan Technological University, Mississippi State University, University of Missouri, Montana State University, Ohio State University, Oregon State University, Pennsylvania

State University, University of Tennessee, Texas A&M University, Virginia Polytechnic Institute & State University, and West Virginia University. These data are being accumulated into a national database and will be merged with data from SSL and made available on the Internet. They are also used to document physical and chemical soil property ranges of soil map unit components and OSDs.

28.2.2 National Soil Information System

NASIS is the transactional database and application used to collect, develop, store, and manage the soil survey data for the NCSS. Information about soil map units and map unit components is stored in NASIS. The data are developed from observations made during field mapping, including reconnaissance observations, transects, grid samples, and field measurements of soil properties. Each soil map unit is composed of one or more map unit components (phases of soil series, other taxa of higher categories, or nonsoil miscellaneous areas). The NASIS database does not limit the number of components within a soil map unit. Each component can have data stored about component percentages, slope, climate, elevation, erosion, flooding, ponding, and performance. Each component can have an unlimited number of soil horizons. Each horizon of a component is characterized by data about physical, chemical, and morphological properties and qualities. Analytical data from the SCD are used to assist in the population of horizon data. Soil interpretation ratings can be generated dynamically for components based on these data. The NASIS design accommodates the relatively easy addition of new data elements to the data model as new needs are identified.

In the NASIS database, soil survey area legends are linked to soil map units. Soil map units are linked to data map units that contain component and horizon level data. This capability is useful in correlation across political boundaries and for the retention of symbols found on earlier versions of maps. This structure also provides the capability of having a set of data available for each delineation (polygon), area, point, or line feature on the soil survey map. The relationship between horizon properties, horizons, components, and map unit polygons and point and line features is shown in Figure 28.2. Component objects and other attributes are assigned to polygons, points, or lines. Table 28.1 lists the physical, chemical, and morphological properties and other data stored either for horizons, components, or map units. To date, there are over 300 data elements.

The NASIS database also stores information about individual detailed soil profile descriptions (e.g., pedons), the site information associated with these descriptions, the relationship or grouping of associated sites, and how soil descriptions relate to transects and traverses. The collection and analysis of these data are essential in the development of soil map unit concepts and their associated components. Soil profile descriptions are linked to associated analytical data in the SCD and can be linked to soil map unit component records.

The soil map unit and corresponding component data are developed in conjunction with soil survey maps, generally at a

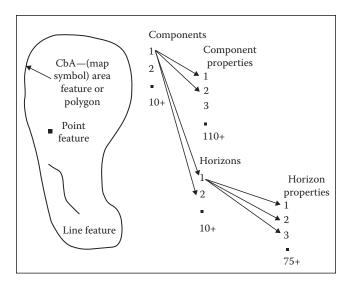

FIGURE 28.2 Data relationships.

scale of 1:12,000–1:24,000. Periodically, datasets are exported from NASIS and certified as official soil survey datasets. These datasets are the source from which most soil survey publications are produced and are provided to NRCS field office computers for use in natural resource planning activities. The data are also used by landowners, private and public land managers, federal, state, and local land use planners, environmental modelers, regulators, and others. The datasets are available through the SDM and WSS.

28.2.3 Official Series Descriptions and Soil Classification Database

The OSDs and associated SC contain the taxonomic classification of each soil series identified in the United States together with other information about the soil series, such as office of responsibility, series status, dates of origin and establishment, and geographic areas of usage. These databases are maintained by the soils staff of the NRCS Major Land Resources Area (MLRA) Soil Survey Regional Offices. Additions and changes are continually being made, resulting from the ongoing soil survey work and refinement of the soil classification system. The series is the lowest level of the soil taxonomic system used in the United States. (Soil Survey Staff, 2006). As the databases are updated, the changes are immediately available to the user, so the data retrieved are always the most current. The data are available through the Internet, which provides the capability of viewing the contents of individual series records, querying the database, and producing a report with the selected soils or national reports with all soils in the database. The standard reports available allow the user to display the soils by series name or by taxonomic classification. Maps showing the geographic distribution of each series can also be displayed. Future plans include the integration of these two databases into NASIS. OSDs are available for more than 23,000 soil series recognized in the United States and are maintained and made available over the Internet.

TABLE 28.1 Soil Data Elements and Interpretive Ratings Included in SSURGO and STATSGO Data

Component data

Component: name, percent, kind

Albedo, dry

Climatic data (MAAT, MAP, FFD)

Drainage class

Elevation

Flooding: frequency, duration, months of the year

Geomorphic setting description

Hydric soil rating and reasons

Hydrologic soil group

Land use: earth cover kind

Parent material

Ponding: depth, duration, frequency, months of the year

Restrictive layers: depth, hardness, kind

Slope: gradient, length, aspect

Soil moisture: monthly depth and status

Soil temperature: monthly depth

Surface rock fragments: percent, size, kind, shape, hardness

USDA Soil Taxonomy classification

Horizon data

Horizon designation and depths

AASHTO class and group

Available water capacity

Bulk density: 1/3, 1/10, 15 bar and oven dry

Calcium carbonate equivalent

Cation-exchange capacity: CEC, ECEC

Electrical conductivity

Erosion factors: Kw, Kf

Excavation difficulty class

Extractable Al and acidity

Free iron oxides

Gypsum

Linear extensibility percent

Liquid limit and plasticity index

Organic matter percent

Particle density

Percent of soil passing #4, 10, 40, 200 sieves

Percent sand, silt, and clay and fractions

Rock fragments: percent, size, kind, shape, hardness

Saturated hydraulic conductivity

Sodium absorption ratio (SAR)

Soil reaction (pH): water, CaCl,

Unified soil classification

USDA texture

Water content: 1/3, 1/10, 15 bar, and satiated

Interpretive and performance data

Crop yields, common crops

Erosion class

Land capability class and subclass: irrigated, nonirrigated

Potential frost action

(continued)

TABLE 28.1 (continued) Soil Data Elements and Interpretive Ratings Included in SSURGO and STATSGO Data

Prime farmland classification

Soil loss tolerance (T factor)

Soil slippage potential

Subsidence depth: total and initial

Wind erodibility index and group

Building site development:

Shallow excavations

Dwellings w/o basements

Dwellings with basements

Small commercial buildings

Local roads and streets

Lawns

Landscaping

Golf fairways

Paths and trail

Construction material:

Road fill source

Sand source

Gravel source

Topsoil source

Forestland management limitations and ratings:

Hand planting suitability

Harvest equipment operability

Haul road and landing construction

Log landing suitability

Mechanical planting suitability

Mechanical site preparation (deep)

Mechanical site preparation (surface)

Natural surface

Potential erosion hazard (off road/trail)

Potential erosion hazard (roads/trails)

Road suitability

Soil rutting hazard

Range and woodland vegetation:

Conservation tree shrub group classification

Ecological site correlation

Plant species composition percent

Plant species, cover percent

Potential production

Site index

Tree species: existing/potential

Recreation development:

Camp areas

Picnic areas

Playgrounds

Sanitary facilities:

Septic tank absorption fields

Sewage lagoon areas

Sanitary landfills

Daily cover for landfills

TABLE 28.1 (continued) Soil Data Elements and Interpretive Ratings Included in SSURGO and STATSGO Data

Waste management:

Land application of sewage sludge

Manure and food processing waste

Waste water disposal by irrigation

Waste water treatment (overland flow)

Waste water treatment (rapid infiltration)

Waste water treatment (slow)

Water management:

Drainage

Embankments, dikes, levees

Excavated ponds, aquifers

Grassed waterways

Irrigation

Pond and reservoir areas

Terraces and diversions

Water quality:

Leaching

Runoff adsorbed

Runoff solution

Wildlife habitat suitability:

Burrowing mammals and reptiles

Crawfish aquiculture

Desertic herbaceous plants

Domestic grasses and legumes

Freshwater wetland plants

Grain and seed crops

Herbaceous tundra

Irrigated domestic grasses and legumes

Irrigated freshwater wetland plants

Irrigated grain and seed crops

Irrigated saline water wetland plants

Riparian herbaceous plants

Riparian shrubs, vines, and plants

Saline water plants

Sedge-grass tundra

Tussock tundra

Upland conifer trees

Upland deciduous trees

Upland desertic herbaceous

Upland mixed conifer/deciduous trees

Upland shrub tundra

Upland shrubs and vines

Upland wild herbaceous plants

OSD is a term applied to the soil description that defines a specific soil series. The OSDs are in a text format and describe general and detailed information about each recognized soil series in the United States, including location, author's initials, introductory paragraph, taxonomic classification, a detailed soil profile description, location of the typical soil profile, range in characteristics, competing series, geographic setting, geographically

associated soils, drainage and permeability, use and vegetation, distribution and extent, where and when the series was proposed and/or established, remarks, and additional data. While doing survey work, field soil scientists use official soil series descriptions that are applicable to their soil survey areas or projects. Other official soil series descriptions that include soils in adjacent or similar survey areas or projects are also commonly used. Thus, OSDs serve as a national standard for identifying and classifying soils and are the basis for the placement of a soil series in the soil taxonomic system. Soil series provide a central concept for soil map unit components, and their names are commonly used in the names of soil map units and map unit components. Scientists in other disciplines, such as agronomists, horticulturists, engineers, planners, and extension specialists, also use the OSDs to learn about the properties of soils in a particular area.

28.2.4 Soil Survey Geographic Database

SSURGO is the digitized version of detailed soil surveys in the United States. The SSURGO spatial data are generally compiled, digitized, and archived at a scale of 1:12,000 or 1:24,000. The minimum-sized area delineated on a map ranges from about 0.6 to 4.0 ha at these scales. The base maps used meet national map accuracy standards and are generally either digital orthophotoquads, quarter-quads, or U.S. Geological Survey 7.5 min quadrangles. The SSURGO database contains digital soil maps, an extensive attribute dataset of physical and chemical soil properties and interpretations that describe each soil map unit and map unit component, and a standard Federal Geographic Data Committee (FGDC) compliant metadata file. SSURGO attribute data are obtained by an export from the NASIS database (Soil Survey Staff, 1995b). SSURGO data are structured for use in a

geographic information system (GIS) and represent the most upto-date, official data of the NCSS for each soil survey area.

Efforts to digitize soil surveys in the United States started in 1971 with the grid cell Map Information Assembly and Display System (MIADS). Soil surveys were digitized in 4.05- and 10.12 ha grids, often along with land use information for the same grid cell. Beginning in 1976, Computervision* software was used to vector digitize soil surveys by either scanning or manual methods. Currently, soil surveys are vector digitized by scanning or heads-up digitizing to meet specified SSURGO standards, using a variety of commercial and public domain software. Some field soil scientists use tablet computers and GIS software to capture soil map unit boundaries in digital format while in the field. This process eliminates the need to later recompile the lines to stable base maps and digitize them.

Starting in 1997, the NRCS began an accelerated effort to digitize all detailed soil surveys and a Presidential initiative provided funding to complete the work. As of 2009, essentially all areas of the United States that have a completed soil survey have been digitized and are included in the SSURGO database. About 90% of the United States is included. These data are available for download from the SDM and can be viewed online via the WSS. The SSURGO data are continually being updated as additional information is gathered by ongoing field operations. An example of an interpretative map based on SSURGO data generated by WSS is shown in Figure 28.3.

28.2.5 U.S. General Soil Map

The U.S. General Soil Map (STATSGO) was designed to be used for broad planning and management in a GIS. An example of an interpretative map generated from STATSGO data is shown in Figure 28.4. Typically, STATSGO is used for state- or region-wide

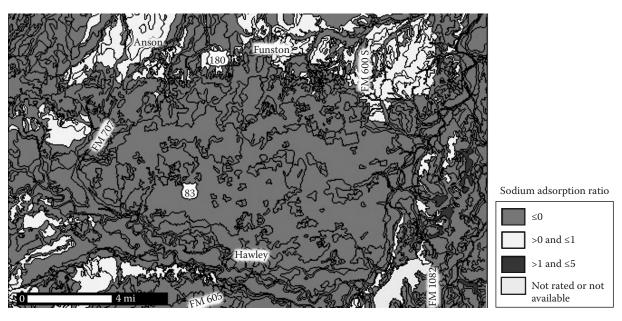

FIGURE 28.3 Soil interpretive map (sodium adsorption ratio of the surface layer) for a portion of Jones County, TX, generated from SSURGO data by WSS.

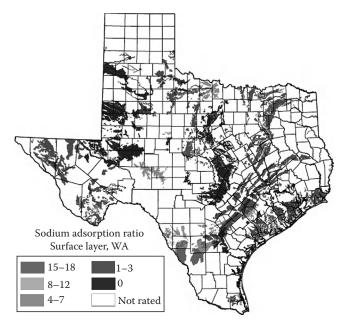

FIGURE 28.4 Soil interpretive map (sodium adsorption ratio of the surface layer) from STATSGO data for the State of Texas.

analysis to identify natural resource and environmental problem areas, prime farmland, potential productivity, global change modeling (carbon maps, etc.), and other uses. STATSGO has also been used to develop resource (staffing and funding) allocation models for NRCS. Several federal agencies, such as the U.S. Environmental Protection Agency, U.S. Geological Survey, and Agriculture Research Service, and many university researchers use STATSGO extensively for small-scale modeling and assessment projects.

STATSGO was developed as the result of NCSS cooperator efforts to create regional general soil maps. The idea for STATSGO was generated at an NCSS work planning conference in 1978. Work on STATSGO began in the mid 1980s and was completed in the mid 1990s. In areas of the United States where detailed soil maps were available, STATSGO maps were made by generalizing detailed county soil survey area maps, which were then compiled and digitized from U.S. Geological Survey 1:250,000 base maps. In unmapped areas, the STATSGO maps were developed using reconnaissance-scale soil survey knowledge and information.

Like the SSURGO data, STATSGO consists of digital soil maps, associated attribute data, and standard format metadata file. STATSGO attribute data are obtained from NASIS exports. The STATSGO map units consist of up to 21 map unit components. NRCS staff assigned a percent composition to each of these components from information in the detailed county-level soil surveys. The minimum-size area delineated on an STATSGO map is about 607 ha (Soil Survey Staff, 1994).

In 2006, the soil property attribute data associated with the STATSGO digital map were updated and converted to the same data structure as that of the SSURGO data. The STATSGO map data were updated somewhat, and the combined dataset was posted to the SDM for distribution. Coverage for the nation is available as are clipped datasets for individual states.

28.2.6 Data Access

SSURGO and STATSGO datasets and associated metadata can be accessed and downloaded over the Internet at http://soildatamart. nrcs.usda.gov/. SSURGO data are also displayed online via the WSS at http://websoilsurvey.nrcs.usda.gov/. Official Soil Series data can be accessed at http://soils.usda.gov/technical/classification/osd/index.html. Soil Characterization data are available at http://soils.usda.gov/survey/nscd/. Linkages to other soil information and to information about the NCSS and the NRCS Soil Survey Program are available at http://soils.usda.gov/.

28.3 The Evolution of Soil Survey Map Unit Databases

28.3.1 The First Generation

The NRCS first established a national soil database in the early 1970s through a cooperative agreement with the Statistical Laboratory at Iowa State University (ISU). ISU was chosen because of its long history of cooperative work with the SCS, dating back to the 1940s. Programming work for a soil database began in 1972 with automation of the soil interpretations records or Form SOI-5, which was used primarily as an input form to generate tables on engineering uses of soils for soil survey reports. Computer programs were developed to store, check, and print the data. The record for the Cecil soil series (NC0018) was the first one stored on the ISU mainframe in 1973. In 1974, the generation of manuscript tables of soil properties for inclusion in soil survey reports was introduced. Initially, all data processing was done at ISU, and a printed copy of the tables was sent through the mail. The SOI-5 forms, along with the SOI-6 forms, which were used to enter map unit information for the soil surveys, were mailed from SCS offices to ISU for processing. Printed copies of revised records and generated tables were mailed back to the SCS office requesting the tables. This automated table generation system replaced a very tedious, time-consuming manual process of creating tables for the published reports.

With the availability of this useful product came a much greater interest in getting data stored in the computer system. In 1977, the capability was added to automatically generate soil interpretations for selected uses from the soil data stored in the database using programmed criteria. After 1977, other enhancements were developed, including the addition of the OSD and Soil Series Classification (SC) databases.

Computerization in SCS offices for processing soil survey data began in 1977 with Linolex word-processing equipment in SCS regional offices. This equipment was used to prepare manuscript tables received on magnetic tape from ISU for final publication. Remote access to ISU from SCS began in the early 1980s with Harris Remote Job Entry equipment in both state and regional offices. Communication was through 4800-baud dial-up commercial ports. This was a time of significant change as batch software had to be redesigned for remote usage and data entry. Processing and printing of manuscripts shifted from ISU to SCS offices.

28.3.2 The Second Generation

Work on the second generation of the national soil database began in 1978, when SCS developed a computer program to rate soils for prime farmland and other important farmland classes and create maps for the Colorado Important Farmlands project. This project required the rating of about 4500 soil map units in Colorado. It used national criteria for prime farmland and state criteria for farmland of state importance and for unique farmland. The most difficult problem was making consistent ratings across soil survey areas. The program evaluated 10 soil characteristics and was fairly accurate in its ratings, but a large database was required to make the ratings, and the effort required to develop the database made the project unfeasible. The need for a large database, which also had to be readily accessible and easy to manipulate, resulted in the development of concepts for the second generation of soil information management.

These concepts were first documented in 1980 in the first technical report for the Colorado Soil Resource Information System (SRIS). SRIS demonstrated the feasibility of integrating several natural resource databases into a common, easy-to-use data environment. SRIS included (1) a soil map unit component database, (2) a soil interpretation database, (3) a pedon characterization database, (4) a climatology database, (5) a plant database, (6) a soil management component, and (7) a schema for the data and description of the system. SRIS was the first effort to manage soil data using a new technology called Database Management Systems (DBMS). This new information system allowed questions relating to more than one natural resource to be answered. It facilitated easy access to soil information and allowed the data to be managed independently of the application software that accessed it, in contrast to the SOI-5 database, which required a computer program to be written for each unique request. SRIS used the System 2000 DBMS, which provided a query language that could be understood and used by anyone with a basic understanding of soil information. In 1982, the soil database was implemented using MicroRim®, later renamed Rbase®, relational database management software (RDBMS).

As an outgrowth of the SRIS effort, SCS established software development staff at Fort Collins, Colorado, in 1985. The mission of this staff was to develop computer software to assist the SCS field office. In 1987, this effort produced the Computer Assisted Management and Planning System (CAMPS) field office software and the State Soil Survey Database (SSSD). SSSD, which used Prelude® RDBMS software, was the culmination of the SRIS effort.

With the release of SSSD, state SCS offices were equipped with UNIX computers. The SSSD software allowed the SCS state offices to manage their portion of the soil survey databases, which were downloaded from ISU via telecommunications. The primary function of the first release of SSSD was to clean up soil data and provide a download of the Map Unit Interpretation Record (MUIR) database to CAMPS. The first release of SSSD provided the ability to develop reports through standard database queries and manage nontechnical soil descriptions.

With this software release also came the recognition that a soil scientist (soil dataset manager) position was needed at each SCS state office to manage the soil information system.

With SSSD, the SCS state offices could edit the soil map unit property and interpretation (MUIR) data at ISU and thus more accurately represent local conditions. The offices then returned a copy of the edited data to ISU. This editing capability provided for a national collection of MUIR data in 1993. SSSD releases in 1988-1993 added additional capabilities. In 1988, the Pedon Description Program, version 1.0, and the Official Soil Series management and soil reports modules were released. In 1989, the interface between the SSURGO database and the Geographic Resource Analysis Support System (GRASS) GIS was released. In 1989, a UNIX mail system called SoilNet and an automated version of the SOILS-6 form, which was used to record map unit data and facilitate the downloading and managing of MUIR data from ISU, were released. In 1991, the Soil Survey Schedule module was released. This module provided management, scheduling, and record-keeping software for SCS state and national offices to use in production soil survey efforts. In 1993, the Hydric Soils, Range Site, and MUIR incremental update modules were released.

Although table generation remained the primary purpose, the MUIR database soon began to be used for more than developing soil interpretation tables for reports. SCS began to use the database to answer questions on a wide range of soil-related issues across the United States, for example, the extent of salt-affected soils, soil loss tolerance, and erosion potential for the determination of highly erodible land, and, more recently, identification of hydric soils (wetlands). The uses of the soil database continued to expand and change until it became apparent in 1988 that SSSD and MUIR could not meet the changing needs. New information systems technology was available that could advance the use of soil survey information.

The MUIR soil database system was remarkable in that it was able to evolve in many ways over time but still kept its basic system design for about 25 years, until it was retired in 1996. At that time, MUIR contained data from about 2,900 soil survey areas and included approximately 250,000 soil map units. Implementation of the replacement system, the NASIS, began in 1994. Before the SSSD system was retired in 1996, the soil information in the MUIR database was converted to the NASIS database.

28.3.3 The Third Generation

Development of NASIS began with the analysis and documentation of the business of soil survey from beginning to end. Teams from various levels in the NCSS were established to complete the requirements analysis. Using structured systems analysis, these teams documented requirements that were passed on to contract software programmers. This analysis documented the important shift of the NCSS from producing static, printed soil survey reports to providing a dynamic database of soil information that could meet a wide range of needs.

A field data collection system was needed to ensure the integrity and completeness of the data collected, including the geographic coordinates. The system was designed to provide users accurate and complete soil survey information based on what was observed during the soil survey process. Implicit in this idea was the ability to describe accurately the variability of soils and their properties as they occur on the landscape. This new system had to provide for a continuous update of the database as new information is gathered, so that one version of these data was available to users at the field, state, and national levels.

NASIS had to provide a means for a variety of scientists to develop interpretations criteria, and generate soil interpretations based on local, state, or national requirements. For example, at the local level, there might be a need for an interpretation of suitability for animal waste disposal, and at the national level there may be a need for a soil productivity index. To ensure consistency, these interpretations must be applied to only one nationally consistent version of the data. The system had to provide for effective and efficient data delivery, including easy access by both internal and external (non-NCSS) users. This information needed to be delivered with a common data structure, data dictionary definitions, and appropriate metadata so that users could understand the information and use it appropriately.

28.3.3.1 NASIS System Objectives

Many weeks of analysis (discussion) early on and numerous follow-up meetings identified the following specific system objectives (Soil Survey Staff, 1991):

- The placement of automated tools in the hands of frontline field office staff
- One-time data entry, so that data could be retrieved by multiple software modules in various computer programs
- A simple means of entering data in same format as that used during data collection
- Validations to ensure proper entry of data and algorithms to provide default values
- Automated procedures for correlation and quality assurance
- Flexibility of the system to adapt to changes in procedure and standards and to new data needs and policies
- Capability to aggregate large-scale digital soil maps to smaller scales based on user-defined criteria
- Data manipulation and retrieval options for all databases and software modules that include modeling capability
- The ability to use single property values or representative values in addition to ranges to be used in models
- Capability to indicate confidence limits and the reliability of map unit data
- Continuous update of national, state, and field office soil survey databases
- Field access to state and national databases at the discretion of the users
- Permanent storage of all soil survey documentation
- Capability to transfer data files between various kinds of equipment

- Two-way linkages to other natural resource databases
- Software modules that are interactive, menu driven, and user-friendly
- Training on how to use the new system

28.3.3.2 NASIS Software Design

NASIS was developed according to an isolated design philosophy that separates the user interface, the NASIS engine, the INFORMIX® engine, and the concepts driven by the data dictionary so that changes can be easily made without reprogramming the entire system. This approach has allowed the easy addition of new capabilities and has permitted the programmers to reuse previously developed codes. NASIS was developed in the C+ programming language using the X Window system, a UNIX-based graphics window system. Similar to the Microsoft Windows® application that comes on many personal computers, the X Window system is a graphical user interface (GUI). This GUI allows users to manipulate the application by means of graphical objects, such as buttons, scroll bars, and icons. A pointing device, typically a mouse, is used. Because NASIS operates in this windows environment, several applications or processes can be run at the same time, each appearing in a separate pane of the window on the screen. NASIS users see a cascading or overlapping that mirrors the hierarchical structure of the data in the soil database.

28.3.3.3 NASIS Security

INFORMIX was selected as the NASIS database management software (DBMS) largely because of its security features. This proprietary design enabled the construction of a system that prevents most accidental or intentional corruption of data. NASIS allows different data records in the database to be owned by different individual users or groups of users, so that only qualified scientists can edit or create data. The owner of an object has the authority to change data as needed. Individual or group ownership can be established as needed.

28.3.3.4 NASIS Software, Hardware, and Network Requirements

The NASIS software and database are located on a central server, and access to it by users requires the same configuration regardless of the user. It requires only a personal computer, an Internet connection, and Citrix® client software for Internet access to NASIS. NASIS is operational in all NRCS state, regional, national, and soil survey project offices, and in the federal, state, and university offices of other NCSS cooperators.

28.3.3.5 NASIS Software Development and Implementation Status

As with the SSSD software, the initial releases of the NASIS software were in successive yearly versions. Version 1.0 was released in 1994. It provided validation and conversion of MUIR to the NASIS database structure, a security system and controls, an operational data dictionary, editors for areas, legends, and data

map units, and online help. Version 2.0, released in 1995, provided cut, copy, and paste functions for data objects, a query editor and manager, global assign functions, report generation, and an enhanced online help system. Version 3.0, released in 1996, provided calculation and validation routines for data and the ability to create interpretations criteria and generate interpretations. The version released in 1997 provided for the replacement of the national MUIR and consolidated NASIS databases from individual state offices to the 18 MLRA Soil Survey Regional Offices. It provided downloads to the NRCS field office computing system (FOCS) and downloads of SSURGO-format datasets. These releases dealt primarily with the development and management of map unit data.

The NASIS version, released in 1998, incorporated capabilities for input of and access to pedon descriptions and soil site information and replicated storage of national map unit data via the Internet at ISU and data sharing via the Internet. In 2001, the NASIS database was consolidated further to a central server environment at the NRCS Information Technology Center in Ft. Collins, Colorado, and data storage at ISU was discontinued. In 2003, the SSURGO data model was adopted and implemented. Periodic releases have continued to add new functionality to the system and to refine the data model as needs change.

Beginning in 2004, development of a new generation of NASIS began. This system is scheduled for release in 2009. It will be a Microsoft Windows system using a .NET® operating system and SQL Server® DBMS. This version will begin managing data by projects rather than the traditional soil survey areas (usually county-based legends). This design will promote designing map units on the basis of their natural occurrence rather than limiting the spatial extent to geopolitical boundaries. As a result, properties, qualities, and interpretations of map units will extend across geopolitical boundaries to their full natural extent.

28.3.3.6 Soil Data Warehouse and Soil Data Mart

Early business analysis for a NASIS identified the need for a single point of delivery of official soil survey data and information and the ability to archive versions of official data. The NASIS database and application are intended primarily for internal use in developing and managing soil survey data, not for public access or delivery of data. To meet this need, the Soil Data Warehouse (SDW) and SDM were deployed in 2003. By that year, significant progress was being made in digitizing soil survey maps. The SDW is designed to hold all versions of official soil survey data (both SSURGO and STATSGO) produced since 2003, including not only tabular attribute data and digital spatial data but also a metadata file that complies with the standards of the FGDC. The SDM contains only the current version of official data and serves as the data-distribution site. It provides a public access point for the data and allows the user either to download digital SSURGO datasets in a standard format for use in a local GIS or to run standard soil survey reports on selected datasets. The SDM can be accessed at http://soildatamart.nrcs.usda.gov/.

28.3.3.7 SSURGO Access Template Database

When data are downloaded from the SDM, the attribute data tables are in a series of unrelated text files. For the data to be used, they first must be loaded into a relational database format of the user's choosing. NRCS has developed a database template in Microsoft Access format for this purpose. The template includes macros for loading the data as well as standard queries and reports for viewing the data. It is included with each download from the SDM.

28.3.3.8 Soil Data Viewer

Soil Data Viewer (SDV) is an application developed as a plug-in extension of ESRI ArcMap for viewing digital soil maps downloaded from the SDM. It requires the SSURGO Access Template Database (described above) for accessing the attribute data. It was developed to help shield the user from some of the complexity of the attribute data structure. SDV includes a series of rules for aggregating soil properties and interpretations for individual map unit components to a single value for the respective map units for display in the GIS-generated thematic maps. This tool is available to the public and can be downloaded from http://soildataviewer.nrcs.usda.gov/.

28.3.3.9 Web Soil Survey

As the digitizing of soil survey maps progressed and the SDM became more fully populated with data, users began to ask why they could not view the soil maps from the SDM online and why they needed to download the data. In response to this need, the WSS was developed. The WSS provides a publicly accessible online interface to the national collection of SSURGO datasets in the SDM. The WSS users can specify their area of interest (AOI), display the soil map for the AOI, generate interpretive maps for a wide variety of uses or selected soil properties, print individual maps or accumulate them into a composite report, or download the SSURGO data for the AOI. The AOI is not limited to part of a single soil survey area but can span multiple survey areas. WSS merges the datasets and displays data and maps in a single layer. WSS uses the same rule set as does SDV for aggregating data for display at the map unit level. A sample interpretive map generated by WSS is shown in Figure 28.5. WSS also provides the capability to download the underlying SSURGO dataset clipped to the AOI boundary for use in a local GIS. Download options are the same as those from the SDM. The WSS can be accessed at http://websoilsurvey.nrcs.usda.gov/.

28.4 Standards for Soil Survey Data

Under the Office of Management and Budget Circular A-16, revised in 1990, the lead agency responsible for coordinating soil data-related activities is the NRCS of USDA. This government-wide leadership for soil data coordination is carried out under the policy guidance and oversight of the FGDC.

NRCS is responsible for developing and implementing a plan to coordinate soil data-related activities among federal

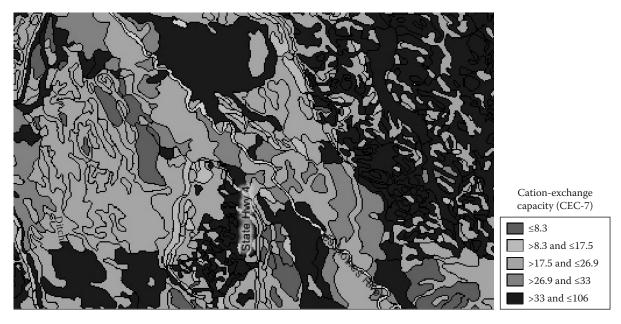

FIGURE 28.5 (See color insert.) Soil interpretive map of weighted average cation-exchange capacity (CEC-7) of the 20–75 cm depth for a portion of Palo Alto County, IA generated from SSURGO data by WSS.

and nonfederal agencies. A soil data subcommittee was established to assist the NRCS in coordinating federal and nonfederal interests in soil data. The subcommittee consists of representatives designated by member agencies of the NCSS that collect or finance the collection of soil data as part of their mission or are responsible for the direct application of these data through legislated mandate. The subcommittee is chaired by the member from the NRCS, Soil Survey Division. It coordinates (1) the exchange of information and transfer of data, (2) the establishment and implementation of standards for quality, content, and transferability, and (3) the identification of the requirements for the collection of spatial data in a manner that minimizes the duplication of effort where practical and economical. Specific responsibilities of the subcommittee include the following:

- To facilitate the coordination of the activities of the agencies related to soil data and the exchange of soil data, by formal and informal means.
- To facilitate the collection and compilation of information for soil data activities.
- To participate in the development and evaluation of data definitions and standards used by the United Nations and other international organizations and make recommendations for their inclusion in soil datasets, as appropriate.
- To identify ways in which soil data from any source may be included in the National Spatial Data Infrastructure.
- To recommend any changes in the definition of soil data that more accurately describe the scope of the data.
- To assist the NRCS in establishing and publishing standards and specifications for the data (e.g., incorporating conversion to metric units) and to assist in establishing priorities for soil data production.

- To assist in the development and adoption of common standards for the content, format, and accuracy of soil data for use by all federal agencies and for encouragement of use by nonfederal organizations. These common standards can increase the interchangeability of the data and enhance the potential for multiple uses.
- To promote government-wide use of defined and published standards for the transfer of spatial soil data.
- To facilitate the economical and efficient application of soil data through the sharing of experiences involving applications.
- To support higher order or cross-cutting activities established or recognized by the FGDC.
- To encourage agencies to schedule the disposition of soil data in coordination with the National Archives and Records Administration in order to facilitate the permanent preservation of historically valuable data.

The subcommittee may create work groups, task groups, or further subdivisions as appropriate to carry out its activities and meet its responsibilities. A work group of this subcommittee has been assigned the responsibility of developing and maintaining the definitions, terminology, and content portion of the Soil Geographic Data Standard. The subcommittee chairperson coordinates activities with other FGDC subcommittees, working groups, and other components by participating in the FGDC's Coordination Group. The FGDC subcommittees and working groups are listed in Table 28.2. To date, standards have been created for the soils data dictionary, soil survey digitizing, and metadata. The Keys to Soil Taxonomy (Soil Survey Staff, 2006), the National Soil Survey Handbook (Soil Survey Staff, 2009), and the Soil Survey Manual (Soil Survey Division Staff, 1993) have

TABLE 28.2 FGDC Subcommittees and Working Groups

Subcommittees	Working Groups
Base cartographic data	Biological data
Bathymetric data	Data clearinghouse
Cadastral data	Earth cover
Base cartographic data	Geospatial enterprise architecture
Bathymetric data	Facilities
Cadastral data	Historical data
Cultural and demographic data	Homeland security
Federal geodetic control data	Metadata
Geologic data	Marine boundary
Ground transportation	Standards

also been designated as standards. These standards are accessible at http://soils.usda.gov/technical/.

28.5 Future Directions for Soil Information Systems

Research, development, and testing are being conducted in several areas that hold a great deal of promise for further use of information system technology in soil survey. The first area is in field data collection. Tablet computers and global positioning system (GPS) technology have been deployed to soil survey offices for use in data collection for both point and map unit data. Pilot projects are underway in which digitized soil survey information is used in conjunction with a grid-point sampling scheme and GPSs in order to provide information on the variability of soils and soil properties on the landscape. The tablet computers will provide for on-screen mapping (digitizing) and the collection of soil data. GIS is being used in the field for premapping and quality assurance of mapping. GIS tools and procedures are being used to generalize large-scale mapping to smaller scales. For example, an updated STATSGO data layer is being proposed to be developed by reclassification or generalization of SSURGO data.

The modern soil survey effort began in the early 1950s in the United States. From then to the present, work by many different people on individual soil survey areas has resulted in a somewhat inconsistent product. Because of a nearly complete SSURGO data layer for the nation and the ability to view the data in GISs, inconsistencies within the data, primarily along artificial soil survey area boundaries, are becoming more readily apparent. The NCSS has started a significant effort of evaluating existing soil survey data across the nation and updating the data

as needed to remove as many of the inconsistencies as possible. New tools are being used by field soil scientists to investigate and remove the inconsistencies.

The NCSS is working to merge the spatial soil data with the attribute database into a common database for further development, enhancement, and management. Pilot studies are underway to identify the workflow processes needed. The goal is to have a seamless SSURGO data layer for the nation. This product will enable more uniform application of various programs and provide better soil data and information to land use planners and decision makers at all levels.

To date, NCSS digital soil maps have been provided in vector format. There is a growing user community who are asking for the data in raster format, which allows much faster analysis operations. Efforts are ongoing with NCSS cooperators, academia, and international colleagues to investigate the feasibility of providing the data in this format.

The biggest challenge for the future will be keeping up with the rapid changes in technology and making the necessary cultural changes in the NRCS and NCSS and to train employees in the use of new technologies. The United States has an estimated \$5 billion replacement cost investment in the soil survey. Information technology will be increasingly used to manage and capitalize on this investment. Finally, information technology and soil survey information will increasingly help to provide solutions as the U.S. population grows and the demand on natural resources increases.

Acknowledgments

The authors gratefully acknowledge the contribution of the following individuals to this chapter and to the development of the U.S. Soil Information System: Harvey P. Terpstra, Statistical Laboratory, Ames, IA; David L. Anderson, Dennis J. Lytle, Gale W. TeSelle, Russell J. Kelsea, Terry Aho, Dorn Egley, Ricky J. Bigler, Sharon W. Waltman, Adrian Smith, Jon D. Vrana, Fred E. Minzenmayer, Ken E. Harward, Ellis C. Benham, Thomas Reinsch, and Dennis Darling, NRCS; and many very dedicated contract programmers.

29.1 Introduction

Large-scale phenomena and impacts, discussed on a global scale under a multiperspective analysis, are increasingly on society's agenda (Pearce and Warford, 1993). Examples directly related to soil science are (1) the expansion of agriculture to areas of tropical forest; (2) the contamination of water resources with residues of pesticides, phosphate, and nitrate used in agriculture; and (3) the degradation of soils through soil erosion (Habern, 1992; Doran et al., 1996; Doran and Safley, 1997).

Additionally, soil scientists are increasingly concerned about global climate changes, where soil organic carbon (SOC) storage is a key issue. To analyze global phenomena related to soil science, we need comprehensive, consistent, georeferenced, and quantitative databases on national or continental scales.

The emergence of integrated digital, spatial, and attribute databases as a credible alternative to fulfill the increasing worldwide demand in spatial soil data is conditioned not only to enhance its ability to increase spatial resolutions and enlarge extents but also to deliver relevant information. Integrated digital databases are an essential part of a soil assessment framework that supports soilrelated decision- and policy-making, and therefore, it is of crucial importance that the mentioned databases are of known quality.

Therefore, the objective of the present work is to gather available information on integrated digital, spatial, and attribute databases for soils in Brazil. In addition, soil maps at different scales at national, regional, and state levels are presented. Some applications of soil digital databases are discussed in order to illustrate potential uses of soil databases in Brazil. Finally, future directions and opportunities are suggested.

.....**29**-25

29.2 Brief Biophysical Setting of Brazil

The Federative Republic of Brazil lies mainly below the equator, in South America, and is broadly bounded by 5°16′N and 33°45′S latitudes and 35°W and 74°W longitudes. It covers 8,514,879 km² or about 48% of the continent, and has over 165 million inhabitants.

A detailed account of the geology is given in Schobbenhaus et al. (1984). Altitude generally does not exceed 500 m as Brazil occurs on an old geologic base without recent tectonics. The highest peak, the Pico da Neblina (3014 m), occurs on the plateau of Guyana near the border with Venezuela.

Brazil can be characterized into five main landscapes: the plateau of Guyana, the Brazilian plateau, the Amazon plain and low lands, the plain of the Pantanal, and plains and coastal lowlands (Ab'Saber, 1996). Knowledge on landforms, soil conditions, and the biota of the Amazon region had remained sketchy until the 1960s (Ab'Saber, 1967; FAO-Unesco, 1971; Sombroek, 1996). A wealth of new information has been gained in the context of the RADAM Project (1973–1982), which covered the entire Brazilian Amazon. It included surveys of the geology, geomorphology, vegetation, soils, and land use. The resulting reports contain results of analyses for over 2500 soil profiles (see Bernoux et al., 2003). While detailed information is available about organic carbon, nitrogen, and phosphorus concentration, soil texture, major cations, and other chemical soil properties, there are few determinations of bulk density (BD) (Bernoux et al., 1998b).

RADAM and other materials were used by EMBRAPA (1981) to compile a 1:5M scale soil map of the country, showing about 2700 map units representing about 70 soil types. Subsequently, EMBRAPA compiled a 1:5M scale soil and terrain database for the country in the framework of the world-encompassing SOTER project (Peters and Van Engelen, 1993).

The 1:5M scale digital soil map of EMBRAPA (1981) uses the Brazilian classification system. On the other hand, SOTER follows the Revised Legend and WRB terminology, facilitating international exchange and correlation. Adoption of a uniform methodology allows using similar procedures for plugging gaps in the measured soil data (Batjes, 2005) and for linking soil parameter estimates to models. The SOTER methodology, albeit with some regional modifications, has also been used to compile a 1:1M database for the state of Rondonia (Cochrane and Cochrane, 1998).

Ab'Saber (1996) and Sombroek (1996) studied the diversity of Amazon landforms and their soils, in relation to biological diversity. Sombroek (2001) also discussed spatial and temporal patterns of Amazon rainfall and possible consequences for the planning of agricultural occupation, and the protection of primary forests. Land use change, the main driving factor that has been described by Lambin et al. (2003), in combination with climate change may have a varying impact on net primary production and, thus, soil carbon stocks in the various natural regions of Brazil (e.g., Moraes et al., 1996; Fearnside, 1998, 1999; Houghton et al., 2000; Cardille and Foley, 2003; Sisti et al., 2004). Many of these aspects are being studied in the context of LBA, the Large Scale Biosphere-Atmosphere experiment (Kabat

et al., 1999). Several authors have reviewed perspectives on sustainable development of the Brazilian Amazon (Clustener-Godt and Sachs, 1995; Cattaneo, 2002; Vosti et al., 2002).

29.3 Soil Maps of Brazil and Description of the Soil Attribute Database

29.3.1 The National Soil Profile Database

Many countries already have soil electronic databases available such as the United States (USDA-National Resources Conservation Service, 2004), Canada (Agriculture and Agri-Food Canada, 2000), and FAO (Food and Agricultural Organization, 1995), but in most countries these data are not available. This is especially true in countries of the tropics.

A digital soil profile database of Brazil was compiled and made available through the internet. Most of the soil data were obtained from the Radambrasil project and other regional surveys. The database contains information from 5,086 profiles distributed over the whole Brazilian territory corresponding to data from 10,034 horizons, each with 31 variables (Figure 29.1).

The variables were chosen to represent different areas of soil science, embracing soil morphological, chemical, mineralogical, and physical attributes. The distribution uniformity of the data was low with sampling densities varying from one profile per $10,000\,\mathrm{km^2}$ to one profile per $1,370\,\mathrm{km^2}$. The access to the database is free and its design allows its use not only by soil scientists but also by those working with agricultural, environmental, and land use issues.

FIGURE 29.1 Brazil's database soil profile location. (Modified from Cooper, M., L.M.S. Mendes, W.L.C. Silva, and G. Sparovek. 2005. A national soil profile database for Brazil available to international scientists. Soil Sci. Soc. Am. J. 69:649–652.)

Due to the large amount of data that were collected and organized, and the objective of developing the database as a multiuser tool, the basic information was compiled in a single text (ASCII format) table to allow a more flexible and user-friendly environment. In this way, any piece of data can be partially or totally added, deleted, edited, or extracted using the database system and structure of the final user's preference.

The sequence used to show the data follows the Radam volumes or that of the institution responsible for the regional soil surveys. This main table contains data from all the soil profiles extracted from the above-mentioned surveys. The profiles are numbered and georeferenced (latitude and longitude in geographic coordinates using decimal degrees with unspecified datum). Each profile contains data of the surface and the diagnostic subsurface

horizons. The variables or soil attributes (Table 29.1) are listed according to a logical order that depends on the type of soil attribute (physical, chemical, or morphological).

Auditing of the database was performed to control the quality of the information. The main errors found in the original publications were typing mistakes, wrong locations, and analytical or calculation errors. The auditing routines were based on those attributes that can be calculated using other analytically determined soil attributes such as cation exchange capacity (CEC) and particle size distribution, or those that can be geographically represented (e.g., latitude and longitude). No quality control was done on analytically determined data. In all the auditing routines, when possible, corrections were made. In the case of various or difficult to correct and missing data, the profiles were eliminated from the final database.

TABLE 29.1 List of Variables Used in the Database with Their Description and Analytical Method of Determination

Database Code	Variables and Soil Attributes	Description	Analytical Method		
ClassifSolo	Soil classification	Soil name according to the 1970 and 1980s Brazilian soil classification system	Field and analytical observations		
DecVal	Slope	Inclination of the surface in relation to a flat reference	Field observation		
Drenagem	Drainage	Velocity at which water is removed from the soil profile	Field observation		
ProfSolo	Soil depth	Maximum soil depth indicated in the descriptions	Field observation		
HzSimb	Horizon type	According to pedological convention	Field observation		
HzProf	Horizon depth	Depth of appearance and disappearance of the horizon	Field observation		
CorMunsell	Color	Described according to Munsell Soil Color Chart	Field observation		
CG	Coarse gravel	Material >20 mm in diameter	Sieving		
FG	Fine gravel	Material between 20 and 2 mm in diameter	Sieving		
Areia	Sand	Particles between 2 and 0.05 mm in diameter	Sieving		
Silte	Silt	Particles between 0.05 and 0.002 mm in diameter	(Sand – Clay)		
Argila	Total clay	Particles <0.002 mm in diameter	Dispersion with NaOH and Sodium Hexametaphosphate, Bouyoucos or Pipette method for determination		
ArgilaNat	Natural clay	Particles <0.002 mm in diameter	Dispersion with H ₂ O, Bouyoucos or Pipette method for determination		
Floc	Degree of flocculation	Proportion of clay that is flocculated	100 (total clay – natural clay)/total clay		
BD	Bulk density	Mass of dry soil per unit volume	Volumetric ring method		
SIO ₂	SiO ₂	Amount of silicon dioxide in soils	Sulfuric attack		
Al_2O_3	Al_2O_3	Amount of aluminum oxide in soils	Sulfuric attack		
Fe_2O_3	Fe_2O_3	Amount of ferric oxide in soils	Sulfuric attack		
pH H ₂ O	pH H ₂ O	pH at a specified soil-water ratio	Soil-water suspension, potentiometer		
pHKCl	pH KCl	pH at a specified soil KCl ratio	Soil-KCl suspension, potentiometer		
С	С	SOC content	Oxidation with K ₂ Cr ₂ O ₇ 0.4 N, Tiurim method		
N	N	Soil total nitrogen content	Kjeldahl digestion		
Ca	Ca++	Exchangeable calcium	Extracted with KCl N		
Mg	Mg^{++}	Exchangeable magnesium	Extracted with KCl N		
K	K ⁺	Exchangeable potassium	Extracted with HCl 0.05 N		
Na	Na ⁺	Exchangeable sodium	Extracted with HCl 0.05 N		
Al	Al***	Exchangeable aluminum	Extracted with KCl N		
Н	H ⁺	Exchangeable hydrogen	(Total acidity-Al+++)		
Tac	Total acidity	Total acidity including residual and exchangeable acidity	Extracted with KCl N		
CEC	CEC	Cation exchange capacity	Bases extracted with NH ₄ OAc at pH 7		
EC	EC	Electrical conductivity	Conductivity meter in a saturated paste of soil and water		

Source: Adapted from Cooper, M., L.M.S. Mendes, W.L.C. Silva, and G. Sparovek. 2005. A national soil profile database for Brazil available to international scientists. Soil Sci. Soc. Am. J. 69:649–652.

One objective for assembling this database was to make available the most comprehensive soil profiles information as possible while using only published data as sources. In this way, information that was restricted to personal or public libraries is being made available through the Internet for noncommercial use. Several variables reflecting chemical, physical, mineralogical, morphological, and pedogenetic features of soil were included, useful for a wide range of topics related to soil science. Of the 31 chosen variables (Table 29.1), 6 correspond to soil morphological attributes, 8 correspond to soil physical attributes, and 16 correspond to soil chemical attributes. To these soil attributes, soil classification of each profile is also included, using the original terminology, completing the 31 variables contained in the database.

The database is useful for soil scientists and other professionals working with agronomy, land-use planning, environmental management, soil process modeling, or any other area in which basic soil data are necessary.

The database is available for free download at http://www.esalq.usp.br/gerd/. The soil taxonomy was updated based on the latest version of the Brazilian Soil Classification System. The coverage and potential for quantitative analyses of the updated database was evaluated by Benedetti et al. (2008). For this purpose, the data were arranged in an electronic database and soil classification updated up to the fourth categorical level of the current taxonomic system. Mainly in the first three levels, the name updating procedure was reliable. Restrictions were observed at the fourth level (subgroup), as measured by the degree of confidence used for the assessment of taxonomic classification accuracy.

By updating the soil profiles to the current and standard taxonomic criteria, the databases were internally standardized and became comparable to external data, for example, spatial distribution, altitude, and climate types. Profiles of the different taxonomic groups nationwide were well represented as well as most federal States (Benedetti et al., 2008).

Furthermore, soil profiles from several taxonomic groups were related to the Köppen climate zones and types (Table 29.2). A relation between the first soil taxonomic level (soil type) and climate was not always evident, with some exceptions, for example, a substantial portion of Vertisols and Alfisols occur in semi-arid climate (BS). The altitude of soil type occurrence was also variable, with some indications of quartile and median preferences for some soils. Inceptisols and Oxisols were more frequent at higher altitudes, whereas 75% of the Spodosols and Ultisols were found below 200 masl. The analysis of the database proposed by Benedetti et al. (2008) can be further complemented for specific study needs, including adaptations to ongoing modifications of the taxonomy of the Brazilian Soil Classification System.

29.3.2 Digital Soil Properties Database of Brazil

The soil and terrain database for Latin America and the Caribbean provided the basis for preparing the present 1:5M SOTER database for the country (BRASOTER). The original geographical and attribute data have been collated into SOTER format by staff of the Empresa Brasileira de Pesquisa Agropecuária—Centro Nacional de Pesquisa de Solos and ISRIC between 1993 and 1997 (Peters and Van Engelen, 1993).

The SOTER methodology allows mapping and characterization of areas of land with a distinctive, often repetitive, pattern of landform, lithology, surface form, slope, parent material, and soils. The approach resembles physiographic or land systems mapping. The collated materials are stored in a SOTER database linked to geographical information system (GIS), permitting a wide range of environmental applications (see Falloon et al., 1998; Batjes and Dijkshoorn, 1999). The SOTER methodology is mainly applied at scales ranging from 1:250,000 to 1:5M.

According to Batjes et al. (2004) each SOTER database comprises two main elements, a geographical component and an attribute data component. The geographical database holds information on the location, extent, and topology of each SOTER unit. The attribute database describes the characteristics of the spatial unit and includes both area data and point data. A GIS is used to manage the geographic data, while the attribute data are handled in a relational database management system (RDBMS).

Each SOTER unit in the geographic database has a unique identifier, called SOTER unit-ID (SUID). This primary key provides a link to the attribute data for its constituent terrain, terrain component(s) (TCID), and soil component(s) (SCID). Each soil component within a SOTER unit is described by a profile (PRID), identified by the national soil experts as being regionally representative. Representative profiles are selected from available soil survey reports as the SOTER program does not involve new ground surveys. A comprehensive description of the methodology and coding conventions is given by Van Engelen and Wen (1995).

Brazil has been described using 298 unique SOTER units, corresponding with 520 mapped polygons. At the small scale under consideration, most SOTER units will be compound units. Some of the spatially minor soil units, however, may be of particular relevance. For example, soils in the Amazon basin

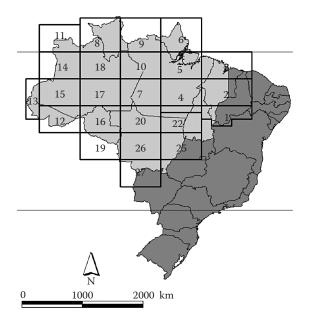

FIGURE 29.2 RADAMBRASIL volume numbers and locations for the Brazilian Amazon.

(Figure 29.2) may be of great importance for national inventories of carbon stocks and change. It is therefore recommended that end-users consider all component soil units of a SOTER unit in their assessments or model runs. Ultimately, the type of research purpose will determine which parameter estimates or single value maps are of importance in a special case. Therefore, the full map unit composition can best be addressed with tailor-made programs depending on the scope of the application.

Gaps in the measured soil profile data have been filled using a step-wise procedure that includes three main stages (Batjes et al., 2004): (1) collating additional measured soil analytical data where available, (2) filling gaps using expert knowledge and common sense, and (3) filling the remaining gaps using a scheme of taxotransfer rules.

Parameter estimates are presented by soil unit for fixed depth intervals of 0.2–1 m depth for organic carbon, total nitrogen, pH(H₂O), CEC soil, CEC clay, base saturation, effective CEC, aluminum saturation, CaCO₃ content, gypsum content, exchangeable sodium percentage (ESP), electrical conductivity of saturated paste (ECe), BD, content of sand, silt, and clay, content of coarse fragments, and available water capacity. These attributes have been identified as being useful for agro-ecological zoning, land evaluation, crop growth simulation, modeling of soil carbon stocks and change, and analyses of global environmental change (Batjes et al., 2004).

The current parameter estimates should be seen as best estimates based on the current selection of soil profiles and data clustering procedure. Taxo-transfer rules have been flagged to provide an indication of the possible confidence in the derived data.

Results are presented as summary files and can be linked to the 1:5M scale SOTER map for Brazil in a GIS, through the unique SOTER-unit code. Most SOTER units in Brazil comprise at least two soil components. In the primary database, the associated information is stored in a range of relational databases to enhance data storage and management efficiency.

All geographic data in SOTER are presented in vector format. However, should grid-based soil layers be required, these can be generated using the convert-to-grid module of the spatial analyst extension to ArcView (ESRI, 1996). The secondary data set is appropriate for studies at the national scale. Correlation of soil analytical data, however, should be done more rigorously when more detailed scientific work is considered.

29.3.3 Digital Spatial and Attribute Databases for Soils in Rondonia and Mato Grosso States

Spatial data were extracted from SEPLAN-RO (1998) and SEPLAN-MT (2002) as sets of electronic files on hypsometry, geology, geomorphology, hydrography, vegetation and soil maps at 1:500,000 and 1:250,000 scale. Hypsometry, geology, geomorphology and vegetation maps were used without any changes. The legend of the soil maps was slightly adapted for consistency.

A single general soil map was made for Mato Grosso using the soil maps at the 1:250,000 scale. All the delineations were conserved. As most map units were similarly coded but their soil content was different, a general legend was established assembling all the original legends of the elementary maps. In the Mato Grosso soil map, the number of soil components of the map units usually ranges from one to two or three, seldom exceeding four. When various components are present, their relative proportions are given in attached tables. Soil components are characterized by their taxonomic type (generally the equivalent of the "soil order" in the Brazilian soil taxonomy), plus texture, vegetation, and slope class attributes.

For Rondônia, we used the unique SIGTERON (Sistema de Informação Geográfico de Terrenos e Solos para o estado de Rondônia) map, which provides spatial units called SOTRO (Solos e Terrenos do Estado de Rondônia). SOTRO are physiographic units delineated on Landsat-5 TM satellite images at the 1:250,000 scale. They are differentiated by a landform type composed of various topographic ("terrain") elements characterized by one soil association. A taxonomic classification (Brazilian and WRB "great soil groups") of the soil components and their relative proportions in the associations were available from attached files. Neither texture and slope nor vegetation is directly referenced. However, information is found in additional SIGTERON files. Slope and vegetation are "terrain" attributes, while texture can be assessed through a soil profile data base. It is noteworthy that in the Rondônia soil map, map units may consist of quite a large number of soil components.

With the complete legend, that is, with all the taxonomic levels and all the classes (with texture and vegetation phases), the number of the soil units is fairly high (425). Without vegetation, the number drops to 147. Only 10 soil units (soil units without vegetation) have a significant extension, more than 2% of the total Rondônia–Mato Grosso area. The spatial extent of the top 8 soil units represents nearly 70% of the total area (Figure 29.3).

Table 29.3 shows the two top "great soil groups" for each landscape region (Figure 29.4) and the number of soil units that belong to each great soil group. The North Rondônia Peneplain (region 1) can be considered as composed basically of two great soil groups—Oxisols ("Latossolo") and Ultisols ("Argissolos"), that represent 77% of the total area (Table 29.3). All are dystrophic, but they are of various color types and various textures. They are represented by 13 and 16 soils units, respectively (Table 29.3).

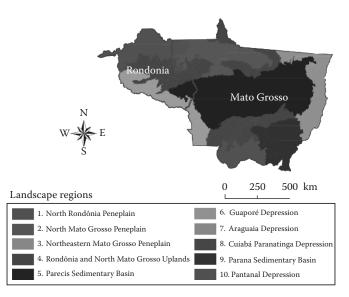

FIGURE 29.4 Rondonia and Mato Grosso states main landscape regions. (Adapted from Volkoff, B., F.F.C. Mello, S.M.F. Maia, and C.E.P. Cerri. 2009. Landscape and soil regionalization in southern Brazilian Amazon and contiguous areas: Spatial pattern for environmental modelling. Scientia Agricola, 2011.)

Many other soil types like Ultisols, gravely soil with ferruginous pisoliths, Inceptisols, and Entisols, are observed (Figure 29.5).

Overall, 69 soil units were identified. The occurrence of Latossolo Amarelo (Xanthic Ferralsol) is one of the characteristics of the region. Oxisol ("Latossolo") soil units have frequently

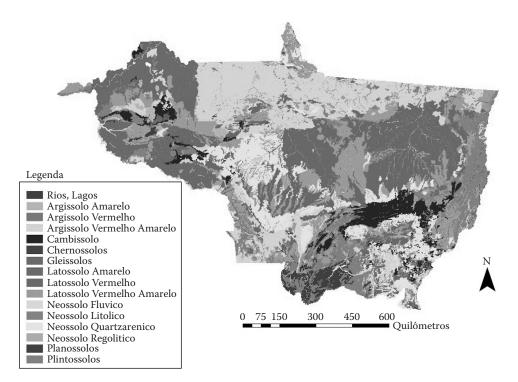

FIGURE 29.5 (See color insert.) Soil map of Rondonia and Mato Grosso states. (Modified from Mello, F.F.C. 2007. Estimativas dos estoques de carbono dos solos nos Estados de Rondônia e Mato Grosso anteriores à intervenção antrópica, 88pp. Dissertation (Master Degree). University of São Paulo, Sao Paulo, Brazil.)

clayey or heavy clayey texture, which is another regional soil characteristic (Figures 29.4 and 29.5).

Regarding its soil cover, the North Mato Grosso Peneplain (region 2) is very homogeneous. It has only one dominant soil unit, the Ultisol "*Podzólico Vermelho-Amarelo distrófico textura media*" (Table 29.3). For this reason, the region can be clearly differentiated from the North Rondônia Peneplain, where Oxisols represent twice the area occupied by Ultisol soils.

The most widespread soil unit in the Northeastern Mato Grosso Peneplain (region 3) is also "Ultisol" Podzólico Vermelho-Amarelo distrófico textura media. This soil is associated with various types of Oxisols, "Solos Concrecionários" and Entisols for a total of 23 soil units. Due to differences in parent rocks, slope and incipient pediment development the soils of the Rondônia and North Mato Grosso Uplands (region 4) show great variability (Figure 29.5). Although the Great Soil Groups are identical, 66% of the area is covered by Oxisols and Ultisols, and the number of soil units is very large, with 100 types listed. There are a great range of Ultisols, and a large variety of Oxisols and Inceptisols and 15 soil units cover 70% of the area. The most frequent soil unit, Ultisol "Podzólico Vermelho-Amarelo distrófico textura média," represents only 13% of the area. This complex spatial soil pattern is one of the characteristics of the region, along with the occurrence of eutrophic soils (mainly, Eutrophic Oxisol and Eutrophic Inceptisol). In addition, it is noteworthy that Oxisol and Ultisols are not always related to leveled topographic surfaces as it is the case in most of the other northern Landscape regions, but they are found here as well as on plane surfaces and on the slopes of rounded hills. They are then of probably differentiated origins. If the topographic parameter were taken into account in the definition of the soil units, the number of soil units should be significantly increased in this region.

The Parecis Sedimentary Basin (region 5) is principally covered by Oxisols (69%) and Entisols. Within the Great Soil Group of Oxisols, several (13) soil units are found. The most represented unit is *Latossolo Vermelho-Escuro distrófico textura media* (Table 29.3). The region is characterized by the predominant occurrence of the Oxisol types, which are all dystrophic. *Latossolo Vermelho-Escuro* and *Latossolo Vermelho-Amarelo* are found indistinctly (Figure 29.5). The texture ranges from clayey to sandy and the heavy clayey texture is atypical. The whole region is almost totally covered by 5 rather important soil units.

The Guaporé Depression (region 6, Figure 29.4) is a very heterogeneous region. The great soil groups Oxisol and Ultisol represent 60% of the total surface (Table 29.3). The variety of soil units is very high, as 86 soil units were identified. For Oxisol and Ultisol, the dominant texture is medium. The large soil diversity and the medium texture of the top soil units are the main characteristics of this region.

The Araguaia Depression (region 7) is another heterogeneous region. The most widespread soils are soils of the great group—Oxisol, with 6 soil units and the most represented soil unit is the great group Ultisol (Table 29.3). The *Plintossolo distrófico textura media* soil unit covers 32% of the area. The great group Alfisol is almost absent. For both the Oxisol and the Ultisol, the dominant texture is medium.

Inceptisol is the main great soil group in the Cuiabá Paranatinga Depression region (region 8). Together with Oxisol, they cover no more than 50% of the total area. Inceptisol is the soil of the central and eastern hilly and mountainous parts. Oxisol occupies the leveled areas of the west (Figure 29.5). Inceptisol and Oxisol units are normally dystrophic and have a medium texture. They are associated with a large range of other soil units, the number of which exceeds 50. The occurrence of Alfisols/Ultisols, "Solos Concrecionários" in the plains and Entisols in the mountain areas must also be pointed out.

In the Paraná Sedimentary Basin region (region 9, Figure 29.4), like in the Parecis Sedimentary Basin region, the dominant great soil groups are Oxisols and Entisols. Altogether they account here for 66% of the total region area while the total was 88% in the Parecis region. This difference is explained by the occurrence of soils (mainly Inceptisols and Alfisols/Ultisols) developed on exposed underlying Paleozoic layers of the sedimentary basin on eroded parts of the plateau. All Oxisols are dystrophic. Latossolo Vermelho-Escuro and Latossolo Vermelho-Amarelo are found indistinctly. The texture ranges from clayey to medium. The main soil unit is Areias Quartzosas distróficas and covers 29% of the total area (Figure 29.5).

In the Pantanal Depression (region 10), Alfisol (essentially 2 soil units) and Ultisol (1 soil unit) are the main represented soils. They account for 80% of the surface (Table 29.3). Excluding the singular Pantanal region, the other landscape regions appear not to be exactly similar with regard to their great soil groups. Although some have only one predominant group (the region 2), they generally have two, that is, Oxisol and Ultisol, that can each occupy the first position depending on the region considered. A better differentiation between the landscape regions can be obtained by considering the soil units. Rarely a single soil unit, sometimes a soil unit association characterizes the soil cover of a landscape region. The soil unit association is generally combined with the occurrence, even if not in predominant position, of one or several specific other soil units. The soil cover can then hardly be summarized by a single soil criterion.

Finally, it is possible to say that for each subdivision, a detailed inventory of the soil units, with their area distribution, can be obtained from soil survey maps at scales of 1:250,000–1:500,000. But this inventory can hardly be used for ecological purposes because of the great number of the soil units, which are generally sparsely sampled. However, this inventory might provide the framework for a stratification of the areal data extracted from soil maps in a new hierarchical classification, the pertinence of which might be tested with related profile data bases. The ensuing increase in the number of observations can then be used in a statistical description of each stratum, making possible the selection of the most relevant stratum to be used for the studied properties.

29.3.4 Digital Mapping of Soil Classes in Rio de Janeiro State

The Rio de Janeiro State is located in the eastern portion of southeast of Brazil, between 41° and 45° of West longitude and

20°30′ and 23°30′ of South latitude (Figure 29.6). With an area of 43.696,054 km², its economy is principally based on services, also with a significant part of industry and little influence in the agriculture sector. In general, the state is divided into two great geomorphologic features; the coastal plain and mountains area, of which eight large landscape types can be identified: coastal plains, north-northwest fluminense, Rio Paraíba do Sul middle valley, mountainous areas, upper Itabapoana river plateau, Serra dos Órgãos, Bocaina, and Mantiqueira (Rio de Janeiro, 2001; Lumbreras et al., 2003).

The Rio de Janeiro State was selected for this work due to the availability of massive georeferenced profile data organized in a data bank, which is unusual in Brazil. For this work, a database was built in Access and Delphi, containing 431 soil profiles derived from the soil survey accomplished by Embrapa Solos in different times. The soils were classified according to Brazilian Soil Classification System at the order level. Of the 13 orders of the Brazilian Classification, 9 orders were identified within the 431 soil profile datasets. Figure 29.7 shows the soil profile distribution in the Rio de Janeiro State. Information about vegetation and landform were also obtained from different works performed in the area over time, which were previously compiled by Carvalho Filho et al. (2003).

In this application, the following covariates were used as predictor variables to build the models: Geocover mosaic (bands 7, 4, and 2 in RGB), freely distributed by NASA (https://zulu.ssc.nasa.gov/mrsid/); the NDVI index (using band 2 instead of 3); Land Use/Land Cover (LULC) map of Rio de Janeiro State, performed by Mendonça-Santos et al. (2003); Lithology class map (Rio de Janeiro, 2001), and srtm DEM 90 m, obtained from the cgiar database at http://srtm.csi.cgiar.org (Jarvis et al., 2006). Detailed information on the digital processing and statistical data analysis are given in Mendonça-Santos and Santos (2008).

Soil classes were predicted by a regression tree (Rulequest Research, 2003). The dataset was partitioned into prediction and validation datasets, being ¾ and ¼, respectively. The program gives the error assessment for both datasets. A tree structure was generated by partitioning the data recursively into a number of groups, each division being chosen to maximize some measure of difference in the response variable in the resulting groups.

Table 29.4 illustrates the main data and information used to build every prediction model (M1, M2, M3, M4 and M5) of soil classes (at the order level), according to *scorpan* factors. All the prediction models were built by regression tree, using the See5 software (RuleQuest Research, 2003), varying the predictor variables. Information was obtained in almost all the factors of *scorpan model* as shown in Table 29.4, including a preexisting polygon-based soil class map (Carvalho Filho et al., 2003) and a Lithology class map.

In order to compare the performance of the models accounting for the number of parameters used, Akaike's Information Criterion (AIC) (Akaike, 1973) was used as a measure index:

$$AIC = -2 \log like + 2 m \qquad (29.1)$$

where

loglike is the log-likelihood of the prediction m is the number of parameters used in the model

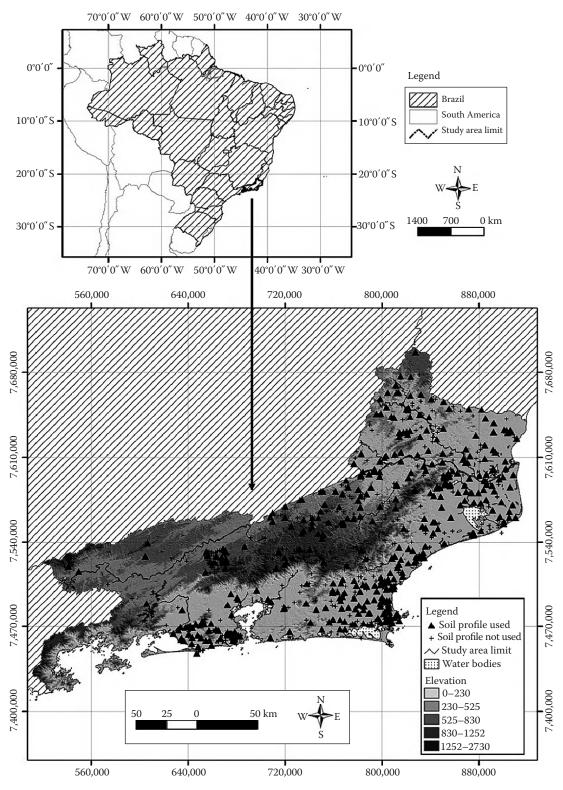

FIGURE 29.6 The study area location and the soil profile distribution on the elevation map, extracted from the SRTM DEM (Jarvis et al., 2006) at 90 m pixel resolution. (Adapted from Mendonça-Santos, M.L., Santos, H.G. dos. 2008. Digital Mapping of Soil Classes in Rio de Janeiro State, Brazil: Data, Modelling and Prediction pp. 381–396. *In A.E.* Hartemink, A.B. McBratney, and M.L. Mendonça Santos (eds.) Digital Soil Mapping With Limited date. Springer, New York.)

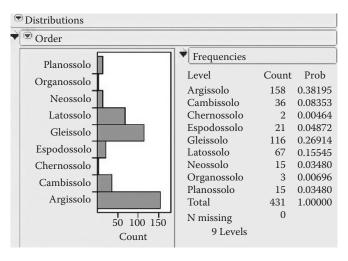

FIGURE 29.7 Soil order and frequency of the 431 soil profiles used in the modeling process. (Adapted from Mendonça-Santos, M.L., Santos, H.G. dos. 2008. Digital Mapping of Soil Classes in Rio de Janeiro State, Brazil: Data, Modelling and Prediction pp. 381–396. *In* A.E. Hartemink, A.B. McBratney, and M.L. Mendonça Santos (eds.) Digital Soil Mapping With Limited date. Springer, New York.)

This index is a compromise between the goodness of fit and the parsimony of the model. The best model is the one that has the smallest AIC.

The log-likelihood for class prediction (k = 1, ..., K) is calculated as follows (Hastie et al., 2001):

$$loglike = \sum_{k=1}^{K} log \hat{p}_k$$
 (29.2)

where \hat{p}_k is the proportion correctly classified as class k:

$$\hat{p}_k = \frac{1}{N_k} \sum I(y_i = k)$$
 (29.3)

N is the total number of data (soil profiles).

In a general way, all models were able to give a good prediction of soil classes at higher categorical levels (order) of the Brazilian Classification showing reasonable error values, which means that soil classes in the study area could be predicted from environmental covariates, that can be easily, cheaply, or even freely acquired, like Geocover images and the srtm DEM 90 m (Models M4 and M5). However, the best model to estimate soil class was the M1, basically due to the use of the existing soil information (polygon soil map). The use of the **S** factor of the *scorpan* model was first proposed by McBratney et al. (2003) but has not been tested as a source to predict soil classes.

Figure 29.8 illustrates the resulting maps for each model. The M1 model was able to predict all the nine soil classes included in the model, with a very good performance (the smallest AIC), as well as their spatial distribution all over the study area (soil classes appear where expected), in a fairly generalized soil map (order level of the Brazilian Classification System).

This work demonstrates that the soil–landscape relationship can be predicted in a quantitative and efficient way, using available information on data sources and existing methodologies in the *scorpan* procedure, which can be useful in areas with lack of or little soil information, as is the case in much of Brazil.

29.4 Integration and Application of Soil Digital Databases in Brazil

29.4.1 Organization and Structure of the Brazilian Soil Information System

The Brazilian Georeferenced Soil Information System (SIGSOLOS) has been developed at the National Center for Soil Research of Embrapa, the Brazilian Enterprise for Agriculture Research, with the support of modern methodologies, techniques, and tools for information management (Chagas et al., 2004). It arose as a recognized necessity from soil scientists, research and development agencies, and agribusiness and environment organizations. The old system for storing information on soil surveys, which had been developed in the 1970s with data

TABLE 29.4 Predictor Variables, Predictive Model, Predicted Variable, and Soil Dataset Information for Each Model Built (M1, M2, and M3)

Models	Predictive Model	Predictor Variables for SCORPAN Model	Predicted Variables	Soil Profiles	Pred_Dataset (3/4)	Valid_Dataset (1/4)
M1	Regression tree	S (Soil classes polygon map) O; (Landsat ETM + 7 Images, bands 7, 4, 3, and NDVI); R (ELEV, ASPECT, PLAN, PROF, QWETI, SLOPE); P (Lithology classes polygon map)	Soil class at order level (13 soil class according to Embrapa 2006)	445	334	111
M2		O (Landsat ETM + 7 Images, bands 7, 4, 3, NDVI and LULC map); R (ELEV, ASPECT, PLAN, PROF, QWETI, SLOPE), P (Lithology classes polygon map)		445	334	111
М3		O (Landsat ETM+7 Images, bands 7, 4, 3 and NDVI); R (ELEV, ASPECT, PLAN, PROF, QWETI, SLOPE), P (Lithology classes polygon map)		445	334	111

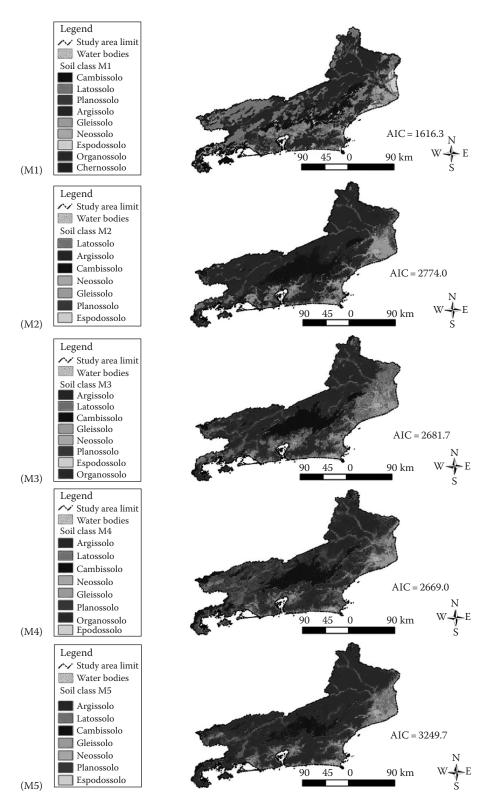

FIGURE 29.8 Resulting maps of predicted soil classes from the five models. (Adapted from Mendonça-Santos, M.L., Santos, H.G. dos. 2008. Digital Mapping of Soil Classes in Rio de Janeiro State, Brazil: Data, Modelling and Prediction pp. 381–396. *In* A.E. Hartemink, A.B. McBratney, and M.L. Mendonça Santos (eds.) Digital Soil Mapping With Limited date. Springer, New York.)

processing techniques oriented to text and numbers, did not satisfy the new requirements from soil science and its applications (Tanaka et al., 1997).

According to Tanaka et al. (1997) and Chagas et al. (2004), the main objectives of SIGSOLOS are (1) the construction of a database of soil surveys and other published works on soil science, as a support for the Brazilian Soil Classification System; (2) the development of new soil mapping models; and (3) the generation of interpretative maps.

The development of SIGSOLOS is the result of the evolution of information technology, based on database management systems (DBMSs) and GISs, in conjunction with the availability of data and metadata through the Internet World Wide Web. Intended, at first, for soil science researchers and students, but designed also for other users interested in a variety of applications, the system provides a visual presentation interface through maps, making a natural interaction with the users possible (Tanaka et al., 1997).

29.4.1.1 The Database

The solution for this kind of problem, through an integrated system with both DBMS and GIS features, is still a research issue in Information Technology. There is no single commercial software product that provides the functionality required by a system like SIGSOLOS (Tanaka et al., 1997). On one hand, DBMSs do not have data types and operators appropriate for all kinds of geographic objects and images. On the other hand, GISs do not have the capability for efficiently managing large amounts of data (Chagas et al., 2004). In order to make the solution adequate to the reality of Embrapa, a strategic design decision was taken to use a dual system architecture that consists in the interaction of an object-relational DBMS—Open Ingres (CA, 1995)—and a proprietary GIS—Spring (INPE, 1995).

Users can access the database directly using DBMS interfaces, through a data entry/query application or through the geographical interface provided by the GIS. The data entry/query is performed with a form-/report-based visual subsystem. Although it has targeted the above-mentioned software products, due to its modularity, this approach allows the use of different DBMSs and/or GISs (Tanaka et al., 1997).

According to Chagas et al. (2004), the database conceptual schema was developed using the well-known entity-relationship model in a database design software tool, making it easy to map the model to any DBMS. The data model was defined during Joint Application Design (JAD) sessions with Embrapa Soil Science researchers and users. The resulting schema is similar to the ones found in the international literature (DeGloria and Wagenet, 1993; Lytle, 1993), with the peculiarities of the Brazilian methodology for soil classification and mapping (Bhering, 1995).

Figure 29.9, from Tanaka et al. (1997), shows the relevant entity and relationship types in the database conceptual schema. The central entity type is WORK that represents three kinds of published works on soil. The most important works are the soil surveys in various levels of detail that describe soil sample profiles,

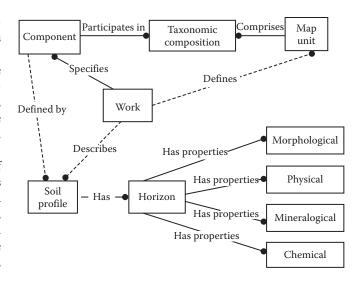

FIGURE 29.9 SIGSOLOS database (simplified) conceptual schema. (Adapted from Tanaka, A.K., S.B. Bhering, and C.S. Chagas. 1997. SIGSOLOS—Conceptual model and future perspectives (in Portuguese), Brazilian Symp. Inf. Agric. Belo Horizonte, Brazil.)

their horizons with morphological, physical, mineralogical, and chemical properties, as well as define map units that comprise taxonomic components based on described or derived profiles. The other kinds of work that SIGSOLOS addresses are technical–scientific ones such as articles and theses that usually deal only with profile information, and reports on derived map generation such as agricultural aptitude maps that use soil profile data described in soil surveys.

In addition to the entity types shown in Figure 29.9, the detailed schema contains diverse data on institutions, authors, municipal districts, and states, as well as dozens of auxiliary tables with attribute domain values. For the sake of simplicity, the diagram in Figure 29.9 is presented at entity type level; some entity types such as WORK, SOIL PROFILE, and COMPONENT may have dozens of attributes. The entity types MAP UNIT and SOIL PROFILE have geographical object identifications that are used as links between the database and its spatial expression—areas for map units and points for soil profiles—in the GIS (Tanaka et al., 1997).

29.4.1.2 Final Considerations

The initially designed application in SIGSOLOS was the support for the parameterization of the Brazilian Soil Classification System. It serves as a tool for classification methodology, at the time of the production soil survey bulletins (CNPS, 1995). Generation of soil maps and derived maps is largely facilitated by SIGSOLOS. Every database-centered information system presupposes, at design time, a set of useful applications. In general, after implementation, data availability and manipulation capability provided by the system raise new, unforeseen demands. With SIGSOLOS, because of the combination of database with GIS features, such new demands have been voluminous (Chagas et al., 2004).

Various versions of the system have been developed, both for client–server workstations and personal computers, and for portable computers to be used in the field. An early prototype of the database was presented at the Latin–American Soil Congress, in August 1996, in Brazil. The system and its conceptual model were presented and discussed during the XXVI Brazilian Congress on Soil Science, in July 1997 (Tanaka et al., 1997).

29.4.2 Regional Organic Carbon Storage Maps of Western Brazilian Amazon Based on Prior Soil Maps and Geostatistical Interpolation

Bernoux et al. (1998a, 2006) and Cerri et al. (1994) studied an area of 334,000 km² of the western Brazilian Amazon basin (Figure 29.10). This area was defined as a 6°-square part of the Brazilian Amazon, from 60° to 66° West longitude and 8° to 14° South latitude, and corresponding to 6.7% of the Brazilian Amazon basin. Administratively, this region corresponds to nearly all the Rondônia state, and small portions of the Amazonas and Mato Grosso states.

The authors organized a specific database from soil profile information reported in published and unpublished soil surveys. The spatial components were derived from two digitized soil maps: 1:5,000,000 soil map and 1:1,000,000 soil map of the region. At this regional scale, the main soil types and their relative extents are similar to that at continental scale. The Ultisols and the Oxisols are the dominant types covering respectively 40% and 34% of the area. The group of Inceptisols, Oxisols, and Alfisols, and the group of Entisols still represent a noticeable extent, accounting for 5% and 3% of the area. The Entisols and Molisols and the Areais quartzosas (Entisols) show extents representing 7.5% and 5% of the total area. In total, these six soil types cover 95% of the area. The main difference between the continental and the regional levels concerns the extent of the Spodosols that represent less than 0.5% in Rondônia and around 2% at the continental scale.

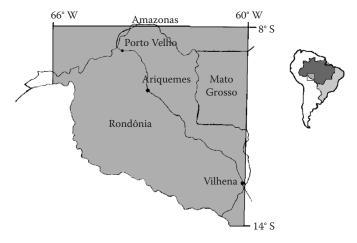

FIGURE 29.10 Location of the western Brazilian Amazon basin.

29.4.2.1 Database and Carbon Stock Calculation for Each Soil Profile

Regarding the soil database and carbon stock calculation, these authors applied a first correction assuming that the soil fraction >2 mm is carbon free. Soil bulk densities were often lacking, and soil carbon content was not always determined for several horizons. Several methods were used to estimate this lacking information. A stepwise multiple regression procedure was developed to predict soil bulk density (SBD) from other properties using the data of 323 soil horizons spread over the whole Amazon basin (Bernoux et al., 1998a). Clay and carbon contents were the best predictors to estimate SBD. For instance, in the case of Oxisols, the use of carbon and clay contents as predictors resulted in a percentage of explained variation near 70%. The following equations were used to estimate soil bulk densities for Oxisols and Ultisols/Alfisols:

1. Oxisols:

BD =
$$1.419 - 0.0037$$
 Clay% $- 0.061$ OC% for A horizons (29.4)

$$BD = 1.392 - 0.0044 \text{ Clay\% for B horizons}$$
 (29.5)

2. Ultisols/Alfisols:

BD =
$$1.133 - 0.041$$
 OC% + 0.0026 S and % for A horizons (29.6)

BD =
$$1.718 - 0.0056$$
 Clay% $- 0.068$ pH_{water} for B horizons (29.7)

The problem of missing soil carbon data was resolved using "power" (Bennema, 1974) and "exponential" (Arrouays and Pelissier, 1994) type equations to model soil carbon distribution with depth. Bernoux et al. (1998b) determined that both models were well adapted for tropical forested Oxisols, but that the "exponential" model is more precise and produces better data. Bernoux et al. (1998a) extend the use of the exponential model to the other Amazonian soil types, mainly the Ultisols/Alfisols. The model equation is

$$\frac{(C(X) - C_2)}{(C_1 - C_2)} = \frac{(e^{-bX} - e^{-bX_2})}{(e^{-bX_1} - e^{-bX_2})}$$
(29.8)

where

X and C(X) are the depth and the C content

 X_1 and C_1 the depth and the C content of a fixed upper position X_2 and C_2 for a fixed deeper position

 X_1 was set to 0 cm, that is, the theoretical contact litter/soil, and X_2 was set to 100 cm; therefore, C(X) could be written as

$$\frac{(CX - C_2)}{(C_1 - C_2)} = \frac{(e^{-bX} - e^{-100b})}{(1 - e^{-100b})}$$
(29.9)

TABLE 29.5 Statistics on C Stock Values (P100 and M100 in kg C m⁻²)

Variable	n	Average	Median	Minimum	Maximum	SD
P100	324	7.30	6.30	0.61	41.62	4.51
M100	424	7.32	6.55	1.50	25.19	3.52

Sources: Modified from Bernoux, M., D. Arrouays, C.C. Cerri, and H. Bourennane. 1998a. Modeling vertical distribution of carbon in Oxisols of the Western Brazilian Amazon (Rondônia). Soil Sci. 163:941–951; Bernoux, M., D. Arrouays, C.C. Cerri, P.M. Graça, B. Volkoff, and J. Trichet. 1998b. Estimation des stocks de carbone des sols du Rondônia (Amazonie brésilienne). Etudes Gestion Sols 5:31–42.

For each soil profile of the database, the parameters of the fitted equation were determined using the nonlinear regression module. Corresponding C stock (M100 in kg m⁻²) was obtained integrating CX:

$$M100 = 10\left(C_2 - (K_1 \cdot K_2) + \left(\frac{K_2}{b}\right) \cdot (1 - K_1)\right)$$
 (29.10)

where

$$K_1 = e^{-100b}$$
 and $K_2 = \frac{(C_1 - C_2)}{(1 - K_1)}$ (29.11)

Soil Carbon stocks (C mass per area) for a given depth were also calculated in a "classical way" for each profile, when data were all available. This classical way of calculating C stock for a given depth consists in summing C stock by horizon, determined as a product of BD, C concentration, and horizon thickness. For each profile, when possible, the corresponding C stock (P100 in kg m⁻²) was calculated not only for the first top meter (Table 29.5) but also for the top 30 cm depth (P0.3 in kg m⁻²), as shown in Table 29.6. Statistics for M100 and P100 gave similar values. The coefficient of correlation calculated among them was 0.972, for 304 profiles with both P100 and M100.

29.4.2.2 Regional Stocks

Cerri et al. (2000) evaluated the regional carbon stocks for the 0-30 and 0-100 cm layers using two different approaches. The first

^a Soil unit.

approach is based on carbon stocks averaged by soil type multiplied by the extent of these soil types. It corresponds to the methodology used by Moraes et al. (1995) and Bernoux et al. (2002).

Using the soil maps, the regional stocks were obtained multiplying the carbon content of each taxonomic unit by its area. This calculation leads to similar results using either the soil map at a 1:5,000,000 scale or the soil map at 1:1,000,000. Regional stocks ranged between 2100 Tg, using median values, and 2400 Tg, using means, and exhibit an associated error (based on standard deviation [SD]) of 900 Tg. Using the map from Embrapa (1:5,000,000) instead of the Radam (1:1,000,000) leads to an increase of only 25 Tg. It is striking that the results are very similar using (1) the median value of all P100 or M100 values or (2) the medians of M100 and P100 segregated by soil type. But in the second calculation, the associated errors based on SD are reduced to less than 50% amount, whereas it reached 71% in the first calculation.

The second approach is based on interpolation of carbon stocks using geostatistics. Geostatistical treatments were carried out using the theory first presented by Matheron (1965) and applied to pedometrics by Burgess and Webster (1980a, 1980b).

Experimental semivariogram for the variables P0.3 and P1.0 were all best (i.e., more satisfactory results of the validations) modeled using a nugget effect plus a spherical model according to the function:

$$\gamma(h) = c_0 + c_1 \left\{ \frac{3h}{2a} - \frac{1}{2} \left(\frac{h}{a} \right)^3 \right\} \quad \text{for } 0 < h \le a \quad (29.12)$$

$$\gamma(h) = c_0 + c_1 \quad \text{for } h > a$$
 (29.13)

$$\gamma(0) = 0 \tag{29.14}$$

where

a is the range of the model

c₀ is the nugget

 c_1 is the sill values

The experimental semivariogram for P0.3 (Figure 29.11) was fitted with a nugget effect of 1.84 (kg m⁻²)² plus a spherical model

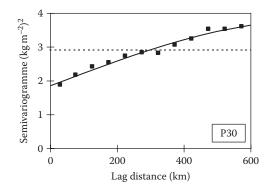

using a sill value of $1.93~(kg~m^{-2})^2$ and range of 772~km. This result shows that carbon densities in the first 0.3~m exhibit a spatial structure at the regional scale. However, the high nugget effect reveals that about half of the spatial variability may appear within distances inferior to a few tens of kilometers. Results of the fitting of the experimental semivariogram for P1.0 show the same pattern with a nugget effect of $4.70~(kg~C~m^{-2})^2$ and a sill value of $4.26~(kg~C~m^{-2})^2$, but the range is reduced to 513~km.

Resulting estimates are very similar, ranging from 2100 to 2400 Tg C in the top meter of soil with the first approach. The geostatistics furnish an estimate of 2220 Tg C, with an associated error of only 13%, compared to a 40% error in the case of soil map-based methods.

Maps of estimated carbon densities and their associated kriged standard deviation (KSD) were calculated by block kriging (Figure 29.12). Each map is made up of 334,107 one km²-square blocks. The P100 kriged values ranged from 4.27 to $10.40\,\mathrm{kg}\,\mathrm{m}^{-2}$, and KSD from 0.54 to $1.31\,\mathrm{kg}\,\mathrm{C}\,\mathrm{m}^{-2}$, the mean values being $6.665\,\mathrm{kg}\,\mathrm{m}^{-2}$. The mean of the kriged values is close to the median of the population of the carbon densities without segregation of soil type. This results in a regional soil carbon content of 2220 Tg C, indicating an intermediary level between the previous estimates, but now the associated error is considerably reduced to 295 Tg, that is, only 13.5% of the amount.

For the carbon stocks in the upper $0.3\,\mathrm{m}$, the kriged values ranged from 2.09 to $6.00\,\mathrm{kg}\,\mathrm{m}^{-2}$, and KSD from 0.36 to $0.76\,\mathrm{kg}\,\mathrm{C}\,\mathrm{m}^{-2}$, their average values being respectively $3.58\,\mathrm{kg}\,\mathrm{m}^{-2}$ (mean) and $0.51\,\mathrm{kg}\,\mathrm{m}^{-2}$ (KSD). The mean of the kriged values is close to the median of the population of the carbon densities for the first $0.3\,\mathrm{m}$ without segregation of soil type. This results in a regional soil carbon content of $1195\,\mathrm{Tg}$, very close to the one previously calculated with the median, but now the associated error is considerably reduced to $170\,\mathrm{Tg}$, that is, only 14.2% of the amount. The geostatistical approach gives regional estimates very similar to those derived from the classical approach based on a soil map, but the advantage of the geostatistical method is to lead to a much lower global associated error and to provide a map of the punctual kriged error.

Bernoux et al. (2006) proposed a third methodology running geostatistical interpolation separately on the parameters of the exponential model fitted for each carbon profile. The three parameters of

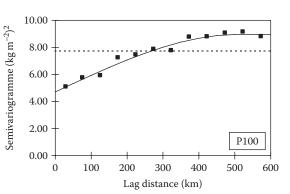

FIGURE 29.11 Experimental semivariograms and fitted models for variables P0.3 and P1.0. (Adapted from Bernoux, M., D. Arrouays, B. Volkoff, C.C. Cerri, and C. Jolivet. 1998c. Bulk densities of Brazilian Amazon soils related to other soil properties. Soil Sci. Soc. Am. J. 62:743–749.)

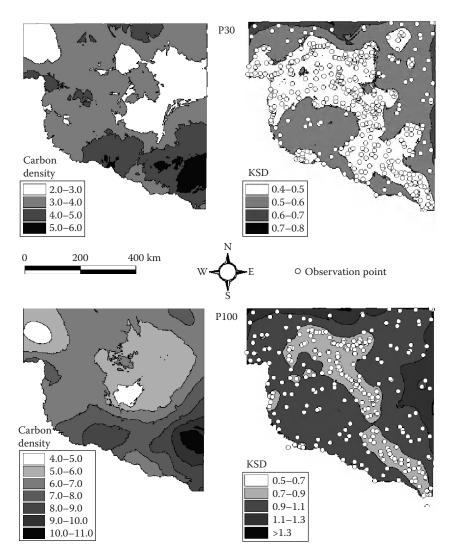

FIGURE 29.12 Carbon stocks down to 1 m depth obtained by block kriging of values (P0.3 and P1.0) and maps of associated errors. (Adapted from Bernoux, M., D. Arrouays, C.C. Cerri, P.M. Graça, B. Volkoff, and J. Trichet. 1998b. Estimation des stocks de carbone des sols du Rondônia (Amazonie brésilienne). Etudes Gestion Sols 5:31–42.)

the vertical model were estimated for 424 soil profiles. Variographic analysis was done independently for each parameters. Results of the variographic analyses showed that the parameters C1 and C2 were spatially structured, but with a high nugget effect. On the contrary, the parameter b relative to the profile curvature showed no spatial dependency. Experimental variograms, corresponding to parameters C_1 and C_2 , were modeled with a linear model with respective nuggets effects of 0.85 and 0.0198 (kg m⁻²)² and slopes of 6.83 10^{-4} and $1.65\ 10^{-5}$ (kg m⁻²)². Even with such high nugget effects, the internal and external validations presented good results.

After validation, the grid of the parameters were obtained by block kriging. Because of the nonlinearity in the profile depth model, conditional simulation might be better than kriging, but kriging procedures were chosen because they can be considered as a more generic tool usable by nonspecialists. Values varied from 1.61 to 3.19 for parameter C1, with a mean of 2.19. Parameters C2 varied from 0.23 to 0.50, with a mean value of

0.31. Associated kriging error represented in both cases from 9% to 23% with a mean error of about 15%.

From the grid parameters it was then possible to calculate the C stocks corresponding to the first top meter. As parameter b showed no structure, two solutions were possible: the use of a fixed value (mean or median of the population) or a moving window average. Population of parameter b is log-normal; therefore, the use of the median was judged more adequate.

This approach was validated by the authors in two different ways. First, a classical external validation using reserved data was employed. The second validation was based on comparing the grid obtained by calculating C stock with the grids for the three parameters, with the grid corresponding to kriging P100 values: the mean deviation was an overestimation of 8.2%.

Finally, it is possible to stress that classical geostatistical approach furnished similar estimates, but with a reduced associated error compared to base-map approach. The new

geostatistical method appeared to be satisfactory, giving an estimate of 2400 Tg C (0–100 cm layer), but with the advantage of estimating soil C stored at any given depth.

29.4.3 Soil Organic Carbon Stocks of Rio Grande do Sul State

The International Panel of Climate Change (IPCC) recommended the implementation of national inventories of greenhouse gas emissions to establish an empirical basis for climate change monitoring (IPCC, 2006). These inventories also provide an invaluable tool to establish mitigation and adaptation strategies in face of climate change. An important usage of inventories is the assessment of temporal changes in SOC stocks by comparison of current with baseline data, usually spatially explicit SOC stocks data prior to human-induced changes. Information on SOC stocks changes derived from different land uses and soil management practices is also critical for the assessment of country-level greenhouse gas budgets (Bernoux et al., 2001; Ministério da Ciência e Tecnologia, 2006).

A protocol suggested by the IPCC for the implementation of national inventories that assigns default SOC stocks to generic soil classes and vegetation types is defined as a Tier 1 method (IPCC, 2006). Tier 2 and 3 methods are increasingly refined approaches using soil pedon datasets from existing soil surveys at finer scales or produced by new field sampling campaigns.

Recent national estimates of baseline and temporal changes of SOC stocks using soil survey databases include Bernoux et al., 2002; Krogh et al., 2003; Bellamy et al., 2005; Lettens et al., 2005. In these studies, regional or national SOC stock maps were derived from soil data of pedon databases with geoprocessing techniques. However, this approach has recognized limitations: soil survey sampling densities might not be adequate for the intended scale of the SOC stock estimate, and sometimes might not cover the diversity and extent of soils; soil sampling protocols and analytical techniques are seldom consistent within databases (IPCC, 2006).

In fact, the most accurate available C analytical techniques, such as dry combustion, were rarely applied in older surveys, and SBD, a critical soil attribute for C stocks calculation was quite often missing. These issues become more critical in less developed countries where systematic soil surveys and soil mapping are generally scarce. For example, in Brazil, a countrywide soil map derived from several regional surveys is available only at a small scale (1:5,000,000) with sparse soil profile coverage. Statelevel soil surveys and maps are mostly in 1:750,000–1:500,000 scale (Giasson et al., 2006).

An important aspect of soil mapping and database management in recent years is the great expansion of personal computers and GIS, which has provided incentive for the conversion of soil maps and databases previously available only in paper format into digital formats. Once converted and validated, these electronic maps and associated databases provide an excellent means for assessment of SOC stocks at spatial and temporal scales. The end-products provide valuable insights for

policymakers to assess compliance with international climate treaties and to establish greenhouse gas mitigation strategies linked to land use and soil management changes.

29.4.3.1 Previous Estimates of SOC Stocks of Rio Grande do Sul State

Rio Grande do Sul (RS), the southernmost state in Brazil, has land area of about 268,897,387 km² (Figure 29.13). The climate is predominantly subtropical with mean annual temperatures ranging from 14°C at higher elevations (>1000 m) in the northeast to 20°C in the western border with Argentina (IBGE, 1986).

The presettlement land covered comprised mostly subtropical and temperate forests, savannas, and wetlands. Current land uses reported include approximately 80,000 km² under agriculture and perennial crops (mainly grain crops, such as soybeans, corn, rice, and small grains) and about 110,000 km² under managed grasslands interspersed with agriculture and plantation forestry. The remaining land area includes native woodlands, savannas, and wetlands (Secretaria Estadual do Meio Ambiente, 2001).

The first estimate SOC stocks in RS is part of the Brazilian National Greenhouse Inventory using the soil map of Brazil (1:5,000,000) and a soil pedon database built from a national natural resources survey (RADAMBRASIL Project) to derive representative stocks for all Brazilian federal states. Tornquist et al. (2004) obtained a new provisional estimate of 1167 Tg original SOC stocks of RA using the Reconnaissance Soil Survey map of 1973 (1:750,000 scale) and the associated soil pedon properties for the 75 mapping units defined in the survey (Ministério da Agricultura, 1973).

FIGURE 29.13 Location of Rio Grande do Sul in South America. (Adapted from Tornquist, C.G., J. Mielniczuk, and E. Giasson. 2004. Estimativa de estoques de carbono orgânico em solos do RS. Anais da XV Reunião Brasileira de Manejo e Conservação do Solo e Águas. Departamento de Solos. UFSM, Santa Maria, Brazil. [CD-ROM] (in Portuguese).)

29.4.3.2 Refined Assessment of SOC Stocks of Rio Grande do Sul

A new estimation of soil C stocks was conducted as a part of a soil C dynamics project in RS, using the most comprehensive soil data available (Tornquist et al., 2009a, 2009b). The Natural Resources Survey of Brazil (Levantamento de Recursos Naturais, better known as the RADAMBRASIL Project) was a wide-ranging national natural resources survey executed in the 1980s. Within the scope of the project, a soil survey was conducted that originated a written compendium—the Natural Resources Report—that included a pedology chapter, which listed soil sampling site descriptions, analytical data of pedons, soil classification, and a state soil map published at 1:1,000,000 scale. The soil map was compiled from field worksheets produced at 1:750,000, preserving the mapping unit delineation. These paper products, including the soil map, have only recently been digitized to GIS-compatible format (IBGE, 2002). However, this digitization process did not include the analytical data of soil classes or soil profiles.

29.4.3.2.1 Data Preparation and GIS Operations

To produce a soil SOC map to a depth of 30 cm, a digital soil pedon database was constructed based on the published RADAMBRASIL survey report. The digital soil maps provided by IBGE consisted of a GIS polygon file containing 1478 records with the attributed soil mapping units, water bodies, urban areas, and sand dunes. For SOC stock estimates, only the 1200 soil polygons representing the spatial distribution of the 44 mapping units were selected.

The calculation of statewide C stocks with soil profile data required compilation of a georeferenced table in GIS-compatible format, in this case ArcGIS (ESRI, 2003). This table included the location of soil pedon (in latitude-longitude format), soil classification, horizon depths, SBD, organic carbon content, and texture of soil profiles listed in the Natural Resources Report. SBD data, which is required for the calculation of soil C stocks, was not included in the RADAMBRASIL soil survey. SBD data was obtained with a pedotransfer function developed for Brazilian soils (Benites et al., 2007):

SBD =
$$1.568 - 0.0005$$
 clay content (g kg⁻¹)
- 0.009 C concentration (g kg⁻¹) (29.15)

$$[R^2 = 0.63]$$

Although strict validation was not conducted for the function, estimated SBD were generally adequate based on SBD from previous field studies conducted in the Soil's Department at Federal University of Rio Grande do Sul. However, estimated SBD of the "Organosolos Tiomórficos" (Hemists) was greatly overestimated, probably because these Hemists lie outside the range of C content and densities of the pedons originally used to develop the function (Benites et al., 2007). A SBD of 0.19 Mg m⁻³

reported for Histosols in RS by Kämpf and Schneider (1989) was used.

The georeferenced table with pedon properties was converted to a GIS point layer and overlaid on the IBGE soil map polygon layer. Soil pedon location and description were visually compared to the underlying soil map polygon soil classification. Pedons with soil classification that did not spatially match with the soil map unit classification were rejected for this project. Pedon data were then transferred to the soil map polygons. The result of this GIS operation was a vector layer (the soil map) with an attribute table that included soil analytical data for each mapping unit. One hundred and twenty-four soil pedons listed in the RADAMBRASIL soil survey report whose geographical location and soil classification matched the mapping units in the soil map were utilized. The soil classes Spodosols and Psamments were not represented in the RADAMBRASIL pedon database and were obtained from other larger-scale surveys in RS.

SOC stocks were calculated by soil horizon as mass of C per area (kg C m⁻²), following the usual procedure: multiplying C concentration, BD, and horizon depth. To attain the depth of interest of 30 cm, in most cases, calculations required either a portion of the surface horizon or the entire surface horizon, and a portion of the next underlying horizon. As a final step, soil classes were aggregated in most cases to the second categorical level of the Brazilian soil classification system. Oxisols and Inceptisols that occur in a very large area of the state, were reported in lower categorical levels. The Spodosol class, which was not sampled and classified in lower categorical levels in the RADAMBRASIL survey, was only reported in the first level. SOC stocks were then averaged by aggregated soil class. SOC stocks for each soil map polygon were calculated by multiplying area (ha) and assigned average SOC stock. Total state C stock in soils was estimated by summing each polygon stock. Mean and median stocks and area weighted mean and median stocks were calculated for each soil class.

29.4.3.2.2 Statewide Estimate of SOC Stocks from Soil Profiles

One of the advantages of a GIS approach to regional SOC stocks estimation is the quick synoptic visualization of the spatial distribution of C stocks (Figure 29.14). In this case, it is clear that SOC stocks were greater in the northeastern part of the state, where a combination of higher elevations (>1000 m), higher rainfall (mean annual precipitation of approximately 220 cm), and temperate climate (mean daily temperatures <22°C) occur. Other areas with high SOC stocks occur near the Atlantic coast and river floodplains in the south central region of RS, were soils are periodically affected by waterlogging.

The geospatial database with SOC information allows the quick calculation of total C in soils of the state, by adding a calculated field with areas under the soil mapping units multiplied by the above C stock estimates. Other calculated fields of interest, including basic statistics, are also possible (Table 29.7). Taking into account the area covered by the soil

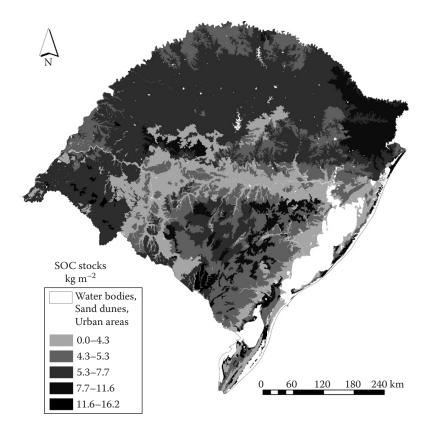

FIGURE 29.14 Soil organic C map of Rio Grande do Sul (0–30 cm depth). (Modified from Tornquist, C.G., E. Giasson, J. Mielniczuk, C.E.P. Cerri, and M. Bernoux. 2009a. Soil organic carbon stocks of Rio Grande do Sul, Brazil. Soil Sci. Soc. Am. J. 73:975–982.)

classes of RS, more SOC was originally present in "Latossolos Vermelhos" (Udox) (294.1 Tg C), "Neossolos Regolíticos" (Orthents) (249.5 Tg C), and "Argissolos Vermelhos" (Udults) (163.7 Tg C), which corresponds to 18%, 15%, and 10% of the total stock. Total terrestrial SOC stock of RS was estimated at 1610 \pm 458 Tg C (1.6 \pm 0.3 Pg C) calculated from soil pedons from the RADAMBRASIL dataset. Mean C density for soils of the state in this project was 7.7 \pm 1.9 kg C m⁻². The total from mean pedon SOC was approximately 1.9% lower and the median was 5.7% than the total stock of 1641 \pm 232 Tg C reported for RS state in the Brazilian National Greenhouse Gases Inventory (Bernoux et al., 2002).

On one hand, this result could be expected, as the dataset used was essentially the same in both studies. The differences were in few soil profiles discarded in this project—those that did not match spatially with the soil mapping units. The result is somewhat surprising, given the finer delineation of soil classes in a larger-scale soil map (1:250,000, compiled to 1:1,000,000) as compared to the Brazilian National Inventory map (1:5,000,000). However, total C stock of RS is mostly determined by a few soil classes, such as Oxisols and Entisols. These two classes are represented by similar areas and SOC stocks in both soil maps.

This pedon-based total SOC stock is 28% larger than a similar earlier attempt to estimate RS state's total SOC stock (1167 Tg C) with a smaller pedon database (Tornquist et al.,

2004). The small number of available pedons (75) and inaccuracies of the Reconnaissance Survey soil map used in that project are possible causes of this underestimation. Mean C density of all soil classes was $7.7 \pm 1.9 \, \mathrm{kg}$ C m⁻² and area-weighted mean was $6.1 \, \mathrm{kg}$ C m⁻². The Brazilian National Inventory reported the same area-weighted median SOC stock of $6.1 \pm 0.9 \, \mathrm{kg}$ C m⁻² for RS.

The SOC digital map and SOC database developed in this research project provide crucial baseline information for conducting state-level contemporary assessment of C stocks and soil carbon sequestration programs and initiatives.

29.4.3.2.3 *Uncertainty*

Soil carbon accounting initiatives have inherent uncertainties that will determine the final accuracy of the estimation of carbon stocks. A general concern with existing databases is the ubiquitous utilization of the Walkley–Black wet combustion analytical method for determining C concentration of soils. It has been shown that a single correction factor, as normally applied in soil C analyses, might not be appropriate for all soil classes, and will lead to the underestimation of C stocks (Skjemstad et al., 2000; Pereira et al., 2006). Soil classes with few complete profiles or missing analytical data also compromise the accuracy of the estimate. Pedotransfer functions are helpful to fill in data gaps, but indiscriminate application is unwarranted and local validation highly recommended.

29.4.4 SOTER Database as Basis for Modeling Soil Organic Carbon Stocks and Changes in the Brazilian Amazon

Land use and land cover changes in the Brazilian Amazon have major implications for regional and even global carbon cycling. Cattle pasture represents the largest single use (about 70%) of this once-forested land in most of the region. The aim of this study was to predict soil carbon stocks and changes in the Brazilian Amazon during the period between 2000 and 2030, using the GEFSOC Modeling System.

The GEFSOC Modeling System (Easter et al., 2007) was assembled under a cofinanced project supported by the United Nations Environment Programme (UNEP) Global Environmental Facility (GEF). The tool was built to provide scientists, natural resource managers, policy analysts, and others with the tools necessary to conduct regional- and country-scale soil carbon inventories. It is intended to allow users to assess the effects of land use change on soil carbon stocks, soil fertility, and the potential for soil carbon sequestration.

The GEFSOC Modeling System was used to integrate the data presented below and to conduct analysis with three well-recognized models and methods: (1) the Century® general ecosystem model, (2) the RothC® soil carbon decomposition model, and (3) the Intergovernmental Panel on Climate Change (IPCC) method for assessing soil carbon at regional scales. The modeling system requires six basic data classes to build the datasets necessary for a regional simulation: native vegetation, historic and current land use management, climate, soils, and latitude/longitude. The Century and RothC models generate large amounts of output. To reduce the size of the dataset while still generating meaningful results for users, the modeling system generates a series of regression statistics for user-defined breakpoints in the management sequence.

The user specifies the years for which soil organic C data are needed in the output dataset, and the modeling system calculates the intercept value, slope, and r² statistic for each time interval between the year breakpoints for the following output data (Easter et al., 2007): (1) Century sum of C in the active,

^a Correlation between the Brazilian Classification System and Soil Taxonomy is only possible at higher levels.

^b Pooled standard deviation.

slow, and passive soil organic matter pools (somsc), (2) Century total soil C (somtc), including belowground structural and metabolic fractions, (3) Century minimum annual total nonliving C (totc), and (4) RothC soil organic C. These data are followed by the mean values for each of the following output variables for the time period between breakpoints: (1) Century growing season accumulator for aboveground C production (agcacc), (2) Century growing season accumulator for belowground C production (bgcacc), (3) Century annual C inputs (cinputs), and (4) Century grain yields. Another output is the results from the IPCC method simulation runs. The soil C stocks and change rates calculated from the IPCC method are obtained using information (land management, climate and soils data) entered into the Graphical User Interface (GUI).

In order to achieve the mentioned goal, Cerri et al. (2007a, 2007b) devised current and future land use scenarios for the Brazilian Amazon, taking into account: (1) deforestation rates from the past three decades, (2) census data on land use from 1940 to 2000, including the expansion and intensification of agriculture in the region, (3) available information on management practices, primarily related to well-managed versus degraded pasture and conventional versus no-tillage systems for soybean, and (4) FAO predictions on agricultural land use and land use changes for the years 2015 and 2030. The land use scenarios were integrated with spatially explicit soils data, climate, potential natural vegetation, and land management units using the recently developed GEFSOC Modeling System.

For soil data, both the soil map of the Brazilian Amazon and the dataset that we describe below were used. The soil map was digitized from EMBRAPA data (1981) at the scale of 1:5,000,000 containing 2698 map units representing 69 soil types for the whole of Brazil. The Soil and Terrain (SOTER) dataset presents

a harmonized set of soil parameter estimates for the Brazilian Amazon, developed to permit the modeling of soil carbon stocks and changes (Batjes et al., 2007). The SOTER database for Brazil (of which the Brazilian Amazon data is part), compiled in the framework of the 1:5M SOTER work for Latin America and the Caribbean, provided the basis for the current study. Results are presented as summary files and can be linked to the 1:5M scale SOTER map for Brazil and Brazilian Amazon in a GIS through the unique SOTER-unit code (Batjes et al., 2004).

29.4.4.1 Regional Simulations

The Brazilian Amazon plays an important role in the global cycle due to its large extent, its relatively high carbon density, and high deforestation rates. As it is well known, there are multiple variables that determine SOC distribution in the Brazilian Amazon. The GEFSOC Modeling System was used to provide estimates of current and future SOC for the entire Brazilian Amazon as shown in Figures 29.15 through 29.17.

Figure 29.15 shows the current SOC stock distribution in the Brazilian Amazon for the 0–20 cm layer, obtained by the Century model. SOC stocks vary from 20 to 150 Mg C ha⁻¹ in the top 20 cm of soil. The majority of the area is under the third class of SOC stocks, that is, from 60 to 80 Mg C ha⁻¹. Figure 29.15 shows agreement with information from other maps. For instance, soils adjacent to the Amazon River have the highest SOC stocks (100–150 Mg C ha⁻¹) due to their hydric conditions. The most northern and southeastern parts of the map show the lowest SOC stocks, which is as expected as the native vegetation is savanna, rather than evergreen forest.

The GEFSOC Modeling System allows estimating SOC stocks, not only for different land uses but also for different soil hydrological conditions. According to SOTER and other data sets for Amazonian soils, the majority of Amazonian soils are nonhydric

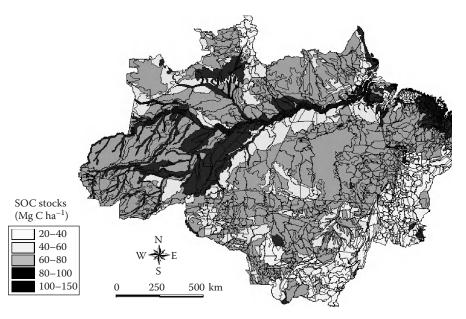

FIGURE 29.15 Map of year 2000 SOC stocks from the Century model for the 0-20 cm layer in the Brazilian Amazon.

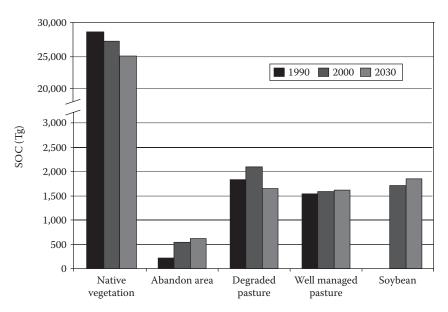

FIGURE 29.16 Modeled SOC stocks in the 0-20 cm layer for the Brazilian Amazon derived from Century (1990-2030).

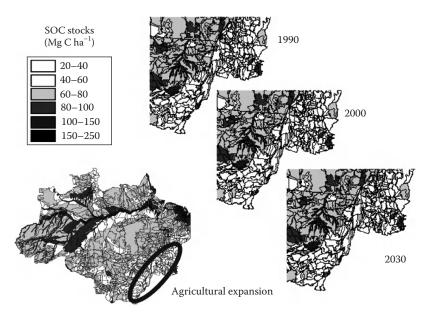

FIGURE 29.17 Estimated SOC stocks in the agricultural expansion area within the Brazilian Amazon (1990-2030).

or freely drained. Among the different land uses under hydric conditions, the largest contribution to SOC stocks comes from soils under native vegetation (mainly evergreen forests, classes colored with black and dark gray, Figure 29.15).

Estimated SOC stocks (0–20 cm) for the years 1990, 2000, and 2030 from Century are presented in Figure 29.16. Stocks of SOC under native vegetation are projected to decrease through time due to the area reduction according to the land use scenarios described earlier. If the projected deforestation in 2030 is realized, approximately 4200 Tg C will be lost from the soil vis-à-vis the estimate for 1990 (Figure 29.16). It should be stressed that following deforestation, large amounts of C are also lost from biomass, much of which is emitted to the atmosphere as CO₂.

According to Dias-Filho et al. (2001), forest-to-pasture conversion releases $100-200\,\mathrm{Mg}$ C ha⁻¹ from aboveground forest biomass to the atmosphere.

In the Brazilian Amazon, areas that have been converted from pasture to agriculture are mainly cropped with soybean, associated with a cover crop (usually millet), and cultivated under conventional tillage during the first 1–2 years before moving to a no-tillage system. Conversion of native vegetation to cultivated cropland under a conventional tillage system has resulted in a significant decline in soil organic matter content (Paustian et al., 2000; Lal, 2002). Farming methods that use mechanical tillage, such as the moldboard plough for seedbed preparation or disking for weed control, can promote soil C

loss by several mechanisms—they disrupt soil aggregates that protect soil organic matter from decomposition (Karlen and Cambardella, 1996; Six et al., 1999), they stimulate short-term microbial activity through enhanced aeration, resulting in increased emissions of CO2 and other radiatively active gases to the atmosphere (Bayer et al., 2000a, 2000b; Kladivko, 2001), and they mix fresh residues into the soil where conditions for decomposition are often more favorable than on the surface (Karlen and Cambardella, 1996). Furthermore, tillage can make soils more prone to erosion, resulting in further on-site loss of soil C (Lal, 2002). Conversely, no-tillage practices cause less soil disturbance, often resulting in significant accumulation of soil C (Sa et al., 2001, Schuman et al., 2002) and consequent reduction of gas emissions (especially CO₂) to the atmosphere (Lal, 1998; Paustian et al., 2000). There is considerable evidence that the main impact occurs in the topsoil with little overall effect on C storage in deeper layers (Six et al., 2002). In the humid tropics, minimum tillage methods may need to be combined with herbicide use for weed control, possibly leading to environmental pollution and a reduction in biodiversity (Batjes and Sombroek, 1997).

Since the adoption of no-tillage systems, SOC stocks are projected to have increased under soybean cultivation (Figure 29.16). The effects of agricultural expansion are evident in the modeled SOC stock change rates (data not shown), where soybean shows the highest change rate among the different land uses in the Brazilian Amazon. There are no estimates for SOC stock change rate or SOC stocks for soybean in the year 1990, as soybean production was not widespread in the region at the time. The projected increase in areas cultivated with soybean that adopt no-tillage systems would lead to an increase in SOC stocks. This is illustrated (Figure 29.17) for the years 2000 and 2030. In 1990, the area of agricultural expansion was dominated by SOC stock class of 20-40 Mg C ha⁻¹. In the year 2000, some areas began to be cultivated with soybean and finally in 2030, most of this region is projected to move to a higher class of SOC stock (40-60 Mg C ha⁻¹; Figure 29.17).

The estimates presented here are comparable with those obtained from other studies considering no-till systems in the midwestern part of Brazil (Riezebos and Loerts, 1998; Vasconcellos et al., 1998; Peixoto et al., 1999; Resck et al., 2000). These studies reported SOC stock accumulation rates of 0–1.2 Mg C ha⁻¹ year⁻¹ for the surface soil layer.

Increased soil C concentrations in surface horizons are a common consequence of pasture formation after forest clearance in the Amazon basin (Bonde et al., 1992; Moraes et al., 1995; Trumbore et al., 1995; Moraes et al., 1996; Neill et al., 1997).

The estimated SOC stocks derived from the GEFSOC Modeling System show SOC stocks slowly increase for well-managed pasture from 1990 to 2030 (Figure 29.16). The area under degraded pasture, that is, areas dominated by herbaceous and woody invaders (Uhl et al., 1988, Serrão and Toledo, 1990) should diminish according to Cerri et al. (2007b) scenarios, mainly due to land prices. This is reflected in the reductions in SOC stocks in the year 2030.

29.4.4.2 Comparison of Current Stocks with Outcome from Existing Methods

There are few studies on estimates of SOC stocks for the Brazilian Amazon (Batjes and Dijkshoorn, 1990; Moraes et al., 1995; Bernoux et al., 2002; Batjes, 2005). Those that are there have focused on soil carbon stocks under native vegetation. According to Cerri et al. (2007a), no prior study has considered stocks of SOC under actual land use (e.g., including areas under pasture and agriculture). Therefore, comparisons between estimates of current SOC stocks obtained using the GEFSOC Modeling System and existing studies do not truly compare like with like. However, given the fact that the outputs from the GEFSOC system for the Brazilian Amazon are unique in terms of the land uses encompassed, it was deemed appropriate to compare them with other available studies, as these represent the state-of-the-art.

29.4.4.2.1 Estimates by Moraes et al. (1995)

Moraes et al. (1995) determined stocks of carbon and nitrogen for soils under undisturbed vegetation across the Brazilian Amazon basin using 1162 soil profiles from the Radam Brasil survey and a digitized Brazilian soil survey map. Mean basin soil carbon density was 10.3 kg C m⁻² to 1 m depth. About 47 Pg C and 4.4 Pg N were contained in the top 1 m of soil. According to the authors, 45% of the total basin soil C (21Pg C) and 41% of total soil N (1.8 Pg N) were contained in the top 20 cm over a 500 Mha area of the Brazilian Amazon. As these data represent sites with forest vegetation in the absence of significant disturbances, they represent a valuable baseline for evaluating the effects of land-use changes on soil carbon stocks in the Amazon.

29.4.4.2.2 Estimates by Batjes and Dijkshoorn (1999)

Soil nitrogen and organic carbon stocks, to a depth of 0.3 and 1 m respectively, were determined for the entire Amazon Region (about 700 Mha) using the soil and terrain database for Latin America and the Caribbean (SOTERLAC, FAO et al., 1995). Mean carbon densities, to a depth of 1 m, range from 4.0 kg m $^{-2}$ for coarse-textured Arenosols to 72.4 kg m $^{-2}$ for the poorly drained Histosols. Mean carbon density for the mineral soils, excluding Entisols and Andosols (30.5 kg C m $^{-2}$), is 9.8 kg m $^{-2}$. In total, the top 1 m holds 66.9 Pg C and 6.9 Pg N.

Approximately 52% of this carbon pool (about 34.8 Pg) is held in the top 0.3 m of the soil, the layer that is most prone to changes upon land use conversion and deforestation. For the Brazilian Amazon (about 500 Mha), the organic carbon stock calculated is 25 Pg C (0–30 cm) and 46.5 Pg C (0–100 cm). For total nitrogen this is 2.3 Pg N (0–30 cm) and 4.9 Pg N (0–100 cm). The figures found for the top 1 m of soil are similar to the ones reported by Moraes et al. (1995).

29.4.4.2.3 Estimates by Bernoux et al. (2002)

The objective of the study by Bernoux et al. (2002) was to give reliable values and a distribution map, for the 0–30 cm reference layer used by IPCC/UNEP/OECD/IEA (1997), for the Brazilian Amazon (an area that was "clipped" from the map of Brazil's

total SOC stock under undisturbed vegetation). In this study, the following steps were performed: (1) elaboration of a map of representative Soil-Vegetation Associations (SVA) for Brazil; (2) organization of a soil profile data base gathering information, such as C concentration, BD, soil type, and native vegetation; (3) calculation of representative C stock (RCS) values for each SVA category and subsequent production of a map of their distribution, and (4) extraction of part of the Brazilian Amazon from the stock produced for the whole of Brazil (Bernoux et al., 2002).

- 1. The Soil-Vegetation Association (SVA) *map* was derived by a combination of the Brazilian soil map (EMBRAPA, 1981) which comprises 2698 map units, split into 69 soil types and vegetation map of Brazil (IBGE, 1988) at the 1:5,000,000 scale. The latter contains 2020 map units divided into 94 vegetation classes by both major groups and subgroups. This map represents the "potential vegetation," that is, the vegetation that could be achieved under current (at the time of the map elaboration) climatic and soil conditions without human disturbance. The strategy of simplification was to use the 12 original major groups as a starting point and to divide them according to vegetation specificity and/or geographical localization. These maps are distributed in digital form by FAO.
- 2. Soil profiles database elaboration: A digitized soil profile database was elaborated by using information published in soil inventories at regional or national scale. Most of the soil profile information came from descriptions of soil pits surveyed by the RADAM-BRASIL project and by EMBRAPA projects at the state level. The soil survey of the RADAMBRASIL project initially focused on the Brazilian Amazon basin and was later extended to the whole of Brazil. The profiles for Amazon Brazil are now available in digital format (Bernoux et al., 2003).
- 3. Calculation of SOC stocks (0–30 cm, kg m⁻²) by profile by summing the C stock of successive horizons in a given profile. C stock in a soil horizon was determined as a product of BD, C concentration, and horizon thickness (for those horizons located in the 0–30 cm depth). Finally, an area was extracted from the Brazil soil carbon stock map (Bernoux et al., 2002) that was consistent with the Brazilian Amazon.

The potential total carbon stock of Brazilian Amazon soils under native vegetation for the $0-30\,\mathrm{cm}$ layer, was calculated as $22.7\,\mathrm{Pg}\,\mathrm{C}$ stored in approximately 500 Mha of the SVA. Using the standard error (SE) calculated for each SVA category (using an arbitrary level of 25% of the representative value when it is derived from only one carbon stock value) as a mean to estimate the accuracy of the total carbon stock, the entire error would be $2.3\,\mathrm{Pg}\,\mathrm{C}$.

29.4.4.2.4 Estimates by Batjes (2005)

SOC stocks were calculated using an updated 1:5,000,000 scale SOTER database for Brazil (Batjes et al., 2004). Each SOTER unit is composed of 1–5 soil components, depending on the complexity of the mapping unit. Individual soil components were characterized by a typical profile selected as being regionally

representative. Use of a single representative profile, however, ignores the variability within a soil component.

Therefore, the procedure included the simulation of phenoforms, using the typical profile as the genoform. The information resulting from the simulations was linked to the soil geographical information through the unique profile identifier for each soil component, to arrive at n (300) realizations of the regional organic carbon stocks. Results are presented as 95% confidence limits for the population median. For the Brazilian Amazon, median SOC stocks to 1 m were estimated to be 42.3–43.8 Pg C of which 23.9–24.2 Pg C occur in the top 30 cm (Batjes, 2005).

Estimates of SOC stocks for the Brazilian Amazon obtained from the different mapping methods are presented in Table 29.2; they are considered to be comparable to, yet lower than those obtained using the GEFSOC Modeling System. The discrepancies may be related to the fact that our modeling results consider possible changes in land use (pasture and agriculture) and management practices (well-managed versus degraded pasture and conventional versus no-tillage soybean cultivation) as opposed to native vegetation only.

Conversely, the mapping approaches implicitly account for possible effects of soil properties other than soil wetness and clay content on SOC stocks, for example, activity of the clay minerals (Wattel-Koekkoek et al., 2001), aluminum toxicity, and content of coarse fragments that are not yet considered in the dynamic models. So, according to Kogel-Knabner et al. (2005), it remains difficult to make unambiguous projections concerning the development of the different carbon pools in soils under changing environmental conditions and land use/management.

A clear advantage of the GEFSOC Modeling System is that it permits the estimation of SOC stocks not only for current conditions, but also for past (historic) conditions and future scenarios. The mapping methods discussed earlier, however, can only calculate SOC stocks for the period for which data is available. They are not dynamic and, hence, do not allow presenting "windows-of-opportunity" for future land use/management scenarios, as required for policy making and in the context of the international conventions.

Estimates of mean SOC density in the top 20 cm layer from RothC and Century models using the GEFSOC Modeling System (4 and 6 kg C m⁻², respectively) are within the range of values presented by previous studies in the Brazilian Amazon. For instance, Bernoux et al. (2002) reported that three quarters of all areas in Brazil had C density varying between 3 and 6 kg C m⁻² for the first 30 cm of soil. Batjes (2005) found mean C densities varying from 2.4 (Entisols) to 9.3 (Oxisols) kg C m⁻² for the 0–30 cm layer for the Brazilian territory.

29.4.4.3 Final Remarks

Pasture productivity and longevity, and agricultural expansion in the Amazon basin are closely related to soil organic matter dynamics. Thus, understanding the major biogeochemical cycles that influence soil organic matter under cleared lands is vital for predicting the consequences of continued conversion of tropical forest to cattle pastures and agriculture. This understanding is also important for devising management technologies that enhance the sustainability of these areas and thus slows further deforestation.

Therefore, more field data is needed on the effect of human-induced land use changes on tropical SOC dynamics and their relationship to soil type and climate condition. Such data can be used together with remotely obtained imagery and geographic information systems and base maps of land use conversions to improve overall estimates of current and future stocks of SOC in the Brazilian Amazon. The GEFSOC system worked well for the conditions in the case study area providing a means of efficiently handling complex interactions among biotic-edapho-climatic conditions (>363,000 combinations) in a very large area (~500 Mha).

Modeling studies, using, for example, the GEFSOC Modeling System, in these pasture and agricultural systems can help us to evaluate the magnitude of these impacts and to determine the effect of possible new management strategies on pasture and cropland sustainability. Our findings for land conversion from forest to pasture/agriculture have important implications, for example, for calculating CO_2 emissions from land-use change in national greenhouse gas inventories.

29.5 Future Directions and Opportunities

In Brazil, research and development has been carried out in several related areas to generate information and technology in integrated digital, spatial, and attribute databases for soils in the country. The first area is in field data collection, in which researchers are exploring new sampling schemes and environmental covariates in digital soil mapping. The second area is related to the use of integrated sensors or some other new technologies for inferring soil properties or status. GIS are being used for premapping and quality assurance of mapping in specific areas of the country. Other areas of interest can be mentioned, such as (1) innovative inference systems (new methodologies for predicting soil classes and properties, (2) GIS tools and procedures are being used to generalize large-scale to smaller scale digital, spatial, and attributes of soils in Brazil, and (3) use of integrated digital, spatial, and attribute database products and their uncertainties for soil assessment and environmental applications.

30.1 Development of Digitized Soil and Land Information Systems in China

Soil mapping is a technique showing the spatial relation of soil types and soil properties visibly, on a sheet of paper or on computer screen. Soil maps, as the product of soil mapping, are important tools in soil resource management and regional planning.

Diversified natural conditions and intensive human activities have endowed China with abundant soil types and land use patterns. Mapping the soil resources in as great a detail as possible has long been a task of the country, striving for a better management of this valuable basis of existence and development, no matter how primitive or advanced the technologies involved. There are several important stages regarding the development of mapping soils of China or inventory of soil data. In general, the generation of soil maps is closely related to the soil knowledge obtained by corresponding activities in a certain time period in meeting the societal demand. Several stages of soil survey and soil mapping can be identified in China up to now.

30.1.1 The Reconnaissance Soil Survey and Marbut Soil Classification Stage

Modern soil science came to China only in the early twentieth century. With the establishment of the Soil Survey Division in the China Geological Survey in 1930, modern soil survey and soil research began. Since then, there have been several major stages of soil survey and soil mapping in China (Li, 1997; Zhang et al., 2008).

The first phase is represented by the early regional soil survey and soil transect studies in the 1930s and 1940s. Since early 1930s, soil survey and soil mapping have been an important part of soil research, among which some regional small and medium map scale soil mapping was conducted. Meanwhile, the national reconnaissance soil maps were planned and tested. At that time, the major guideline followed the (agro)geological point of view for soil regionalization and soil mapping. With the introduction of modern soil classification concepts and principles by American pedologists, such as J. Thorp, who helped conduct soil survey in several regions in China, the Marbut soil classification was adopted. In the county and smaller areas, soil series were used as mapping legends, with soil group becoming the most accepted. For small-scale soils maps, "soil region" and "subregion" were adopted. In 1935, J. Thorp published his Soil Geography of China, which is the first monograph of its kind documenting the major soil types and their general distribution pattern, according to Marbut soil classification system. In order to show the abundant and complicated soil types and soil resources of China, Ma Y.T. and his colleagues started with many studies about soil cover and soil cover structure, soil complexes, and soil association. In 1934, Ma Y.T. proposed "soil area" concept and illustrated it in his early mapping practices. The 1:10 M Soil Map of China classified soils into 11 great groups and created 2 distinct categories: pure soil or complex soil. That map covered the whole territory of China, except for a small portion of the high and frigid regions in the Qinghai-Tibetan Plateau, which for the first time showed more or less the complete picture of the general soil distribution pattern of China and put forward a classification of alpine soils. Moreover, special delineations were also made to incorporate paddy soils in the lower Yangtze and Huai River valleys. The naming of paddy soils was first proposed by Hou and Ma, (1941). In 1949, another small-scale soil map was created by Ma and others. The 1:8 M soil map categorized 60 soil areas and subareas for which major bioclimate zones and soil types were used to classify soil areas and major soil associations for subareas. In these soil maps, soil classification and soil regionalization were combined and the mapping legends were mainly related to regions. Between 1946 and 1949, in the soil regionalization of the Yellow River Valley and that of China, bioclimatic zone, soil zone, soil complex, and soil catena were used. All these reflected the main thoughts of small-scale soil mapping in that stage (Zhang et al., 2008).

Other than the above mentioned maps (see Figure 30.1), many other mapping activities and products were developed during this stage. In 1947, Zhu compiled The Generalized Soil Map of Jiangxi Province, with a scale of 1:6 M (Zhu, 1948). Zhu and Hesung also compiled the 1:6 M Generalized Soil Map of China, using soil region and region complex.

30.1.2 The Russian School Stage

The second phase started with the foundation of the People's Republic of China in 1949 and spanned from the 1950s to the 1960s.

This phase is characterized by the use of zonal soil distribution theory and deepening soil mapping studies. Russian genetic soil zonal distribution theory fully embraced in China as well as soil mapping. Legends used in small map scale soil mapping such as "soil region" and "subregion" were shifted to pure soil classification units. On the other hand, there was an accumulation of knowledge about soils of China, especially the classification of soils going into more detail by which more and more soils were identified and classified that greatly improved the understanding of soil types and their distribution. In 1955, the newly compiled 1:4M "Generalized Soil Map of China" by the Russian soil scientist Gerasimov (co-authored by Ma) clearly reflected the pedogenetic point of view and the zonal distribution of soils in China and the shift of mapping legend from complex and association to pure soil types (Li, 2007). This map classified 42 mapping units at the great group levels, among which 32 were located on plain area, the remainder being found in mountainous regions. The map pointed out that the pedogenetic features of mountain soils are different from that of plain soils. This facilitated soil classification and mapping basis. Therefore, in the first published soil map of China, mountain soils and plain soils were divided into two major groups. Besides the general soil map showing soil distribution, the idea of providing service

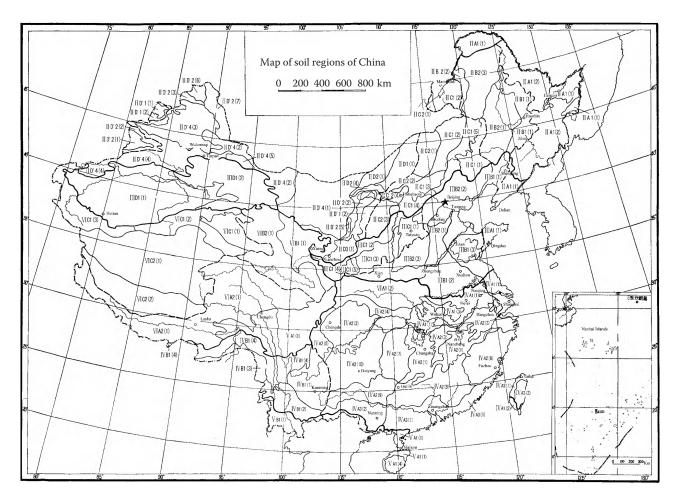

FIGURE 30.1 The soil region maps of China, generated in 1956, by Ma Y.T., Institute of Soil Science, Chinese Academy of Sciences.

to agriculture was adopted into the project and medium to large map scales maps of soil texture, soil nutrient content, soil reaction, carbonate content, etc., were compiled. Those thematic maps provided important soil information for regional soil management and agricultural development (Ma, 1960; Zhang et al., 2008).

With the increasing demand for soil information, potential forestry and agricultural land exploitation, soil and water conservation, and soil survey and mapping programs were implemented rigorously, which enabled the rapid accumulation of regional soil geographical data. This progress was apparent in the 1959 version 1:4 M Soil Map of China, which clearly showed the geographical distribution with a great deal more data. Up to 1965, soil maps were formally collected in the National Atlas of China in which 129 mapping units were established. Many upland soils, in addition to several paddy soils, were emphasized. However, due to the overemphasis of the zonal distribution principle, the reality that soil distribution is complicated and spatially variable was not well reflected, especially on cultivated soil types.

Many regional soil maps were produced during this stage, in order to meet the demand of regional natural resource exploitation and economic development. For example, a series of soil maps and soil erosion maps, ranging from a map scale of 1:5000, 1:10,000 1:200,000, to 1:1,000,000, were produced for soil and water conservation in the loess plateau of the middle Yellow River valley (Ma, 1960). Similarly, in the middle and lower reaches of the Yangtze River, soil survey programs generated medium-scale soil maps to meet the demand of catchments planning and irrigation programs. In the Huai River valley, the major problem in land reclamation was the flooding hazard in those low lying areas. In order to develop irrigation program, several soil survey programs were conducted during several different time periods, which generated 1:200,000 soil maps and soil regionalization maps as well as soil geology maps of the major irrigation regions. These maps provided a very important service to water resource planning and irrigation programming. In northeastern China, due to the need of potential arable land exploration and wind erosion control as well as that of forest development and watershed planning, regional soil reconnaissance survey and detailed survey in key areas were conducted. The detailed and medium-scale soil maps and other thematic maps, including those indicating soil parent materials, land use, groundwater mineralization degree and quality, soil salinization level, and soil reclamation regionalization, were produced based on the surveys. The detailed soil maps were mainly made for state farms and forestry farms in northeast China, on which maps covering the whole area were compiled. In Xinjiang, comprehensive soil survey programs were conducted, which completed the provincial small- and medium-scale soil maps and soil regionalization maps of several key areas, with emphasis on the genesis, classification, properties, distribution, and amelioration of saline soils. The area of potentially arable land was estimated and land management measures were proposed (Ma, 1960).

South and southwest China was mapped with medium-scale soil maps. For the key areas, the detailed maps were again provided. The small-scale Central and South China soil maps and soil regionalization maps were compiled based on surveys in those areas. The main applications of these maps were to meet the requirement of tropical and subtropical crop suitability regionalization and to provide resource statistics and planning of land resources.

Based on the regional soil survey and soil mapping practices, the national soil distribution principle was studied and the 1:4,000,000 soil maps and soil regionalization maps of China were compiled (Ma, 1957; Gerasimov et al., 1958). Soil regionalization classification system was established, which included Soil Climate Zones (First Class), Soil Bioclimate Regions (Second Class), Soil Regions or Subregions (Third Class), Soil Areas or Provinces (Fourth Class), Soil Groups (Fifth Class), etc., facilitating national, provincial, and even regional soil regionalization.

30.1.3 The National Soil Survey Stage

The third phase refers to a rapid development period that occurred between the late 1970s and 1980s, during which soil mapping theory and methodology were emphasized, revolutionizing the soil mapping system with the development of remote sensing application in soil resource survey and soil mapping. Begun in the middle and late 1970s, with the recovery of basic and applied research in China, soil mapping research, including both mapping theory and methodology, was closely followed. This allowed new/modern concepts such as the soil mapping system, its division, polygenetic mapping principle, as well as the comprehensive legend system to be incorporated into national soil research techniques (Li, 1988). Until the mid-1980s, a number of national, regional, and multiple-scale soil maps were compiled, among which the Soil Atlas of China was compiled using the serial mapping method. This atlas reflected the up-to-date knowledge of all disciplinary results of soil science in China (Hseung and Li, 1986).

In this period, experimental remote sensing based soil mapping was conducted, especially using visual interpretation of remotely sensed images. Automated mapping according to videotaped remote sensing data was also used commonly. Regional soil maps and land use maps were compiled using satellite imagery data (Lin, 1981). The most updated national 1:1 M Soil Map of China, which was based on nationwide soil survey as well as extensive remotely sensed data, has become the most detailed national soil map.

The second national soil survey program mobilized all levels of soil science in China, covering the whole mainland territory and all land uses. Township level, county level, and province level soil maps, typically in the scale of 1:10,000, 1:50,000, and 1:250,000, were compiled frequently during this period. These maps have become the most important sources of many current soil information systems. In the meantime, very small-scale maps, such as 1:4,000,000, 1:10,000,000, and 1:18,000,000 maps, were made for the whole country. The *Soil Atlas of China* by ISSAS (1986) collected a series of soil type and soil attribute maps.

30.1.4 Soil Database and Information System Stage

The fourth phase is the soil information system and digital soil mapping stage that started in the late 1980s and extends to the present. From the late 1980s to the early 1990s, technological advancement led to the integration of geographical information and soil information as a geo-referenced soil information system. This has dramatically changed the methods of traditional soil mapping. Thanks to the ever-increasing processing power of computers, soil maps have become soil information systems by which large amounts of attribute data become readily available for widespread use. Mapping technology, objects to be included, attribute data, as well as the scope of map interpretation had undergone a revolutionary change. Many important soil databases have been built since then.

In the 1980s the Remote Sensing Center of Peking University tried to establish a soil erosion information system. In the early 1990s, the creation of such a soil database began a new era of soil research. In 1991, a Regional Soil Information System (RSIS) was built and applied by the Institute of Applied Ecology, Chinese Academy of Sciences (CAS) (He and Hou, 1991). In 1992, the Institute of Soil Science, CAS (ISSCAS) established 1:500,000 Hainan soil and terrain database (SOTER) (Zhou, 1994). Actually, with the introduction of SOTER methodology into China, several SOTER databases, including 1:4,000,000 national SOTER and 1:500,000 provincial SOTER of Jiangsu and Shandong were constructed (Zhang et al., 2001a). A more detailed scale, the 1:200,000 SOTER of Hainan Island-HaiSOTER, was started in 1998, under the collaborative efforts of ISSCAS and ISRIC (Gong et al., 2001; Zhang et al., 2001d). As a more complete land information system, SOTER integrates soil and terrain information and is regarded as a useful tool for land suitability evaluation (van Engelen and Wen, 1995; Dijkshoorn et al., 2008). SOTER methodology was introduced into China in the mid-1990s, and by 2002, the 1:200,000 provincial Hai-SOTER was built and applied for agricultural land management (Mantel et al., 2003; Zhao et al., 2003), which was almost the first medium-scale SOTER in the world.

The 1:1 M SOTER of China was recently constructed and has been used for land degradation study in combination with other data sources. The topography of the 1:1 M SOTER was interpreted according to the 90 m resolution SRTM data (CGIAR-CSI, 2004) that was available at the time. Based on the images, parameters like altitude and slope and relief intensity were extracted according to standard SOTER description (Dobos et al., 2005). The overlay of the above three parameters can delineate the terrain units for the SOTER database. Soil data comes from the 1:1 M soil information system of China (Shi et al., 2004b) and with reference to FAO soil mapping legend (FAO-Unesco, 1988). Point data of more than 3000 pedons, including morphological data and physical, chemical, and mineralogical data, were collected and linked with the SOTER units by referring to the parent materials and landform as described in the soil database. By doing so, every SOTER unit has at least one typical soil profile linked, which allows further thematic soil property mapping and other sophisticated land evaluation.

The early twenty-first century has witnessed the rapid development of soil information systems in China. The digitized 1:4,000,000 soil map was not adequate to meet the ever-increasing demand of digital soil information. A more detailed soil information system, the Soil Information System of China (SISChina) was initiated and completed by ISSCAS, covering 1:1,000,000 spatial data, pedon attribute data, as well as the soil reference system of soil classification (Shi et al., 2007b). Up to this point, the serial soil databases of China covered 1:14,000,000, 1:4,000,000, 1:2,500,000, and 1:1,000,000 scale soil maps and their corresponding pedon data. For provincial and local regions, 1000 soil geochemical maps and trace element distribution maps were digitized and constructed as usable databases. SISChina incorporated more than 7000 pedons and more than 1 million bits of attribute data, enabling the creation of secondary soil property maps measuring attributes such as soil pH and soil texture (Shi et al., 2004a). The 1:1 M Soil Map of China is now a part of the Harmonized World Soil Database (HWSD) (FAO/IIASA/ISRIC/ISSCAS/JRC, 2009).

Based on the second national soil survey of China conducted in the 1980s, a much more detailed soil information system, using 1:50,000 map scales, is being built. As many of those detailed paper maps are stored in counties across the country, they are being lost or damaged physically due to inappropriate storage, which implied the overlooking of soil information in the past years. The rescuing work of collecting and digitizing the valuable maps (more than 2000 sheets of maps) is a huge project. Currently, more than 60% of county-scale maps in the 1:50,000 scale have been merged into an integrated soil database, covering about half of the country territory geographically (Figure 30.2).

In short, the development of soil mapping and soil information systems have undergone drastic changes since the 1930s and 1940s and is outlined as Figure 30.3, which shows how soil mapping has evolved and what uses the soil data has facilitated.

Entering the new millennium, the development of the everrecognized digital soil mapping (DSM) technology has become one of the most important advances in basic soil geography. The core of DSM is the quantitative soil–environmental relationships and their application in soil mapping. Through the integration of digitized soil-forming covariates (McBratney et al., 2003), it is possible to automate soil identification and soil mapping in various resolutions, according to expert rules and/or quantitative algorithms. Similarly in China, DSM is being tested in various pilot regions (Yang et al., 2007; Zhao et al., 2007), to provide a methodological and technical basis for future digital soil mapping.

30.2 Use of Soil and Land Information Systems in China

30.2.1 Soil Status Assessment

Soil databases are important bridges, linking basic soil studies and their applications to other agriculture fields. Since the late 1980s, a series of regional and national soil databases have

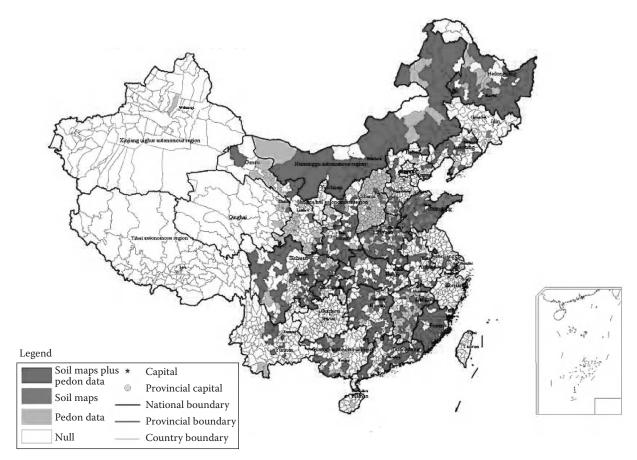

FIGURE 30.2 (See color insert.) The coverage of digitized 1:50,000 soil maps of China. (Courtesy of Dr. Weili Zhang, Institute of Soils and Fertilizer, Chinese Academy of Agricultural Science, unpublished.)

been established, which are used extensively in natural resource exploitation, land use and agricultural planning, environmental protection, and ecological restoration, on regional and national scales. Given their flexibility in manipulating data using various application models, applications of soil databases were employed extensively. Basically, the applications covered the single factor analysis, synthesized analysis, and model-based applications.

30.2.1.1 Single Factor Analysis

Single factor analysis mainly involves the spatial variability of soil properties, such as pH and soil texture as well as nutrients and their stocks. These applications primarily involve the soil database itself and require nearly no other related data.

The soil pH value varies across the country, clearly reflecting the general decrease of soil pH from the north and the northwest to the south and the southeast (Figure 30.4). A series of important soil management measures can be drawn from such maps, for example, for the allocation of chemical fertilizer resources or for the use of suitable fertilizer types. For example, because low soil pH is often related to high soil iron and aluminum oxides, phosphorus fertilizer efficiency is low in south China. Therefore, calcium magnesium phosphate was recommended as early as the 1950s.

This kind of single factor analysis also applies to many other soil properties, such as soil organic matter variation, and soil phosphorus content and availability. However, it should be pointed out that the areal result of rasterized soil pH values, and other similar soil properties, is obtained by the interpolation of point data of more than 3000 pedons. The uncertainty of the extrapolation is to be assessed.

30.2.1.2 Multiple Factor Analysis

Other than a single soil property manipulation, multiple soil factor analysis involves the calculations of more than one soil property. Taking soil organic carbon stock assessment as another example, soil database application provides an important role in systematically calculating the stock and the spatial distribution of soil organic carbon. The basic formula for calculating SOC stock is

$$S = \sum C_i D_i \rho_i \tag{30.1}$$

where

S (kg m⁻²) represents total SOC stock within one square meter of a given soil down to a certain depth

 C_i is the SOC content (kg kg⁻¹)

 D_i is the depth of horizons (m)

 ρ_i is the soil bulk density (kg m⁻³)

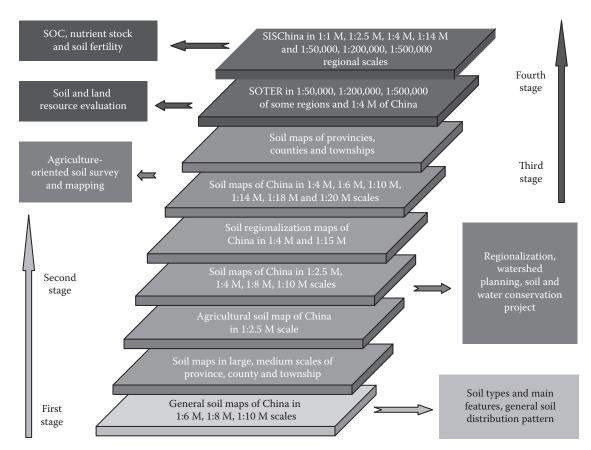

FIGURE 30.3 The major stages of soil mapping and soil database construction in China and their main uses.

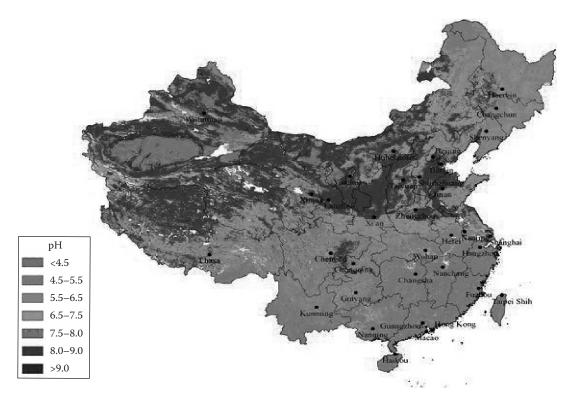

FIGURE 30.4 Soil pH map of China as obtained by database operation. The data source comes from the digitized 1:1 M Soil Map of China.

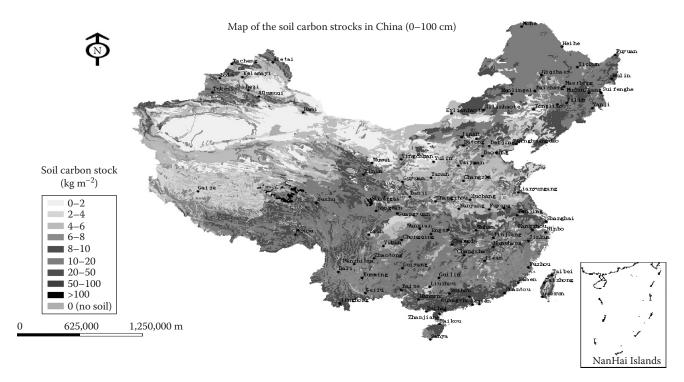

FIGURE 30.5 Soil carbon density at 100 cm depths in China. (Courtesy of Dr. XIE Xianli, Institute of Soil Science, Chinese Academy of Sciences.)

All necessary variables of such a calculation, including soil organic carbon content of soil layers, bulk density, gravel content, as well as the depth of layers, are stored in a typical soil database. The basic manipulation of the soil database allows the calculation of the overall density (kg m $^{-2}$) of organic carbon at a given depth. Multiplying the density by the area the soil represented in a GIS context, the total SOC reserve of a given area is easily obtained. Moreover, the spatial distribution of such a result can be visibly illustrated via a map.

Figure 30.5 shows the calculated results of SOC density (Kg m⁻², 1 m depth) of China, based on the digitized 1:4 M soil map and the supporting pedon data (Xie et al., 2004). The averaged SOC density is 9.14 kg·m⁻², varied from less than 2 kg·m⁻², to more than $100 \, \text{kg} \cdot \text{m}^{-2}$. The total stock of SOC amounted to 84.4 Pg. Another similar study, facilitated by the 1:1 M soil map of China, showed that the average density is about $9.60\,kg\cdot m^{-2}$ and the total stock about 89.14 Pg (Yu et al., 2005). These calculations gave a fairly good estimation of SOC storage in China and clearly showed the spatial distribution of the density, which provided policy makers with an idea of how much carbon was sequestrated in soils while also showing potential regions for further carbon sequestration by possible agricultural and engineering measures. However, both of those results were not able to show any uncertainty estimation during the calculations, because normally, there were only a very limited number of pedon data available for a given map unit or delineation, which prevent further intra-unit analysis.

30.2.2 Land Suitability Assessment

Land quality evaluation is important for soil and land management. The qualitative land evaluation methods, such as ALES (automated land evaluation system) (Rossiter, 1990), were used quite often. Land quality assessment involves multiple factors and criteria, such as soil fertility assessment, soil quality assessment, land suitability assessment, and soil erosion risk assessment. The basic procedure for such analysis is to first determine the assessment entity, for example, a map unit, followed by evaluation factors and selection and assessment models (Figure 30.6). The core data source of such assessment relies normally on soil information, which is an often limiting factor.

The basic mapping unit for such an evaluation varies according to the objectives. Besides the normal soil mapping units, which are either soil types or association of complex soil types, SOTER units have become new assessment objectives. Given the characteristics of combining terrain classes, geology (lithology), and soil types, SOTER units can best describe the physically homogenous areas where similar soils developed on same geological background in similar terrain segments (van Engelen and Wen, 1995). The advantage of SOTER units in land evaluation is that they are more operational than a single soil area in terms of being more complete in reflecting actual land conditions.

A series of land evaluations were conducted in China and applied to various regions and map scales, including soil fertility, soil quality, soil erosion risk, and the suitability of crops in different scenarios. In order to facilitate a sustainable agricultural land management policy, comprehensive land evaluation was recently conducted in the tropical Hainan Island.

Based on the integrated SOTER databases at the map scales of 1:500,000, 1:200,000, and 1:50,000 (county level only), the suitability of tropical crops, including banana, coffee, rubber,

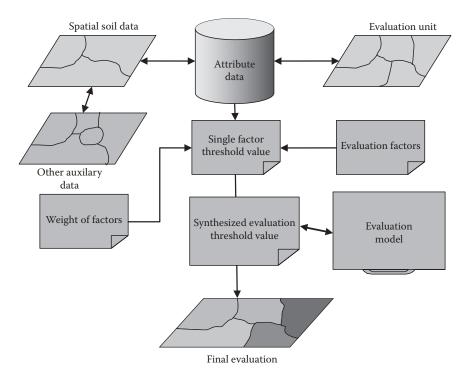

FIGURE 30.6 Land suitability assessment based on multiple factor analysis of soil databases.

mango, and several other tropical fruits, was assessed, by using ALES as the basic land evaluation model (Zhang et al., 2001c). Moreover, other evaluation tests, including soil quality as defined mainly by physical and chemical fertility (Zhang and Zhang, 2005), the current soil erosion risk and the potential erosion under different land use scenarios (Zhao et al., 2003), and soil diversity (Zhang et al., 2003), were also conducted.

30.2.2.1 Soil Quality Assessment

Soil quality has been viewed in two ways: first, as an intrinsic or static property of a soil governed by natural soil-forming processes, and second, as a dynamic state or health of a soil that reflects its condition under a specific management system (Karlen et al., 1997). Numerical soil quality assessment is an effective decision-making tool for land users to identify the best management practices (Karlen et al., 1997). During the last 10 years, a systematic method of soil quality assessment has been developed. This method includes three main steps: (1) identifying appropriate soil quality indicators for a minimum data set, (2) transforming those indicators into dimensionless standard scores, and (3) incorporating the indicator scores into soil quality indices (Andrews et al., 2002).

Inappropriate use and management have caused severe degradation of soil quality in the tropics (Lal, 1990). Therefore, the assessment of soil quality is urgently needed to reverse degradation (Stocking, 2003). Here we take Hainan Island, the second largest island and the largest tropical region of China, as an example, to show how regional soil quality variation can be differentiated based on the existing SOTER database.

Standard scoring functions (SSFs) suggested by Karlen and Stott (1994) were used to transform soil properties into dimensionless scores (Zhang and Zhang, 2005). For each soil quality indicator, the types and parameters for the SSFs were determined by expert opinion as recommended in the literature (Wang and Gong, 1998; Hussain et al., 1999; Glover et al., 2000).

In this study, soil quality was evaluated in terms of four soil functions: water availability, nutrient availability, rooting suitability, and erosion resistance with reference to a combination of the methods of Karlen and Stott (1994) and Harris et al. (1996). Indicators in minimum data sets were grouped to determine the four functions. The weightings of each indicator and of each soil function to the overall soil quality index were assigned based on expert opinion (Table 30.1).

According to above soil functions and indicators as well as their weights in the calculation, the soil quality of Hainan Island was estimated (Figure 30.7). From the result it became apparent that the outer part of the island has a low soil quality, which is explained by their very low nutrient score (Zhang and Zhang, 2005).

30.2.2.2 Soil Erosion Risk Assessment

The assessment of soil erosion risk is also a multiple factor analysis. Currently, soil water erosion models, such as SWEAP (Soil Water Erosion Assessment Program), USLE (Universal Soil Loss Equation), and Revised USLE are being used, although they are not tailored for regional use. SWEAP was developed specifically for SOTER, from which soil erosion factors, such as rainfall, soil organic matter content and texture (erodibility), slope and slope length, etc., can be extracted from the database. Figure 30.8 shows

TABLE 30.1 Table Additive Weightings Used to Calculate Indices of Soil Functions and Overall Soil Quality

Function	Weight	Indicator	Weight
Water availability	0.25	Clay content	0.3
		Bulk density	0.3
		Total organic C	0.2
		Water stable aggregates	0.2
Nutrient availability	0.25	Total organic C	0.3
		CEC	0.2
		pH	0.2
		Extractable P	0.1
		Exchangeable K	0.1
		Microbial biomass C	0.1
Rooting suitability	0.25	Soil depth	0.3
		Bulk density	0.3
		% Clay	0.2
		pH	0.2
Erosion resistance	0.25	Water stable aggregates	0.35
		Total organic C	0.35
		% Clay	0.3

the general procedure of soil erosion risk assessment using USLE. The result is a rough estimation as USLE is based on a single slope. Nevertheless, such a result is useful in knowing the relative risk categories (van den Berg, 1992).

For the actual operation, the spatial database is composed of SOTER unit, climate zone, and land use maps. Three kinds of base maps (1:100,000 landform map, 1:200,000 lithology map, and 1:200,000 soil map) were selected to compile the SOTER unit map. Two routes for field check were conducted to confirm the reasonability of the SOTER unit map. In total, 185 SOTER units were identified on Hainan Island. Relating to 19 county climate stations, 19 climate zones were delineated based on average temperature, accumulated temperature, and average 30 year typhoon rainfall data. Climate data, monthly precipitation, minimum and maximum temperatures, relative humidity, radiation, and evaporation, from the 19 stations, were included in the database. Climate zone and SOTER unit maps were integrated to get the agricultural ecological unit (AEU) map. Land use data were obtained from SPOT satellite images where landcover classes were converted to land-use classes according to the standard SOTER methodology.

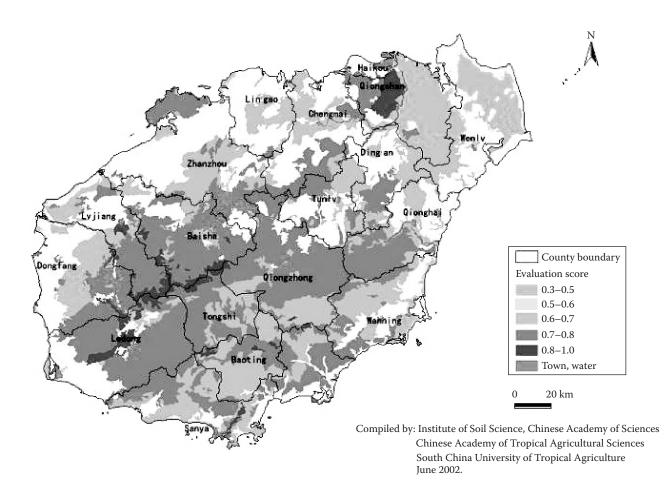

FIGURE 30.7 Soil quality assessment of Hainan Island.

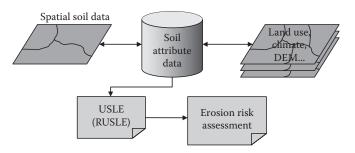

FIGURE 30.8 Scheme of soil water erosion risk assessment using SOTER and USLE.

Many bits of attribute data were needed for soil erosion evaluation. The evaluation model obtains climate data from a climate database, land use information from the base map as well as basic data (such as slope length, slope gradient, organic carbon content in the fine earth fraction, weight of silt, weight of very fine sand, soil structure and profile-permeability) from the SOTER database. Classification names and definitions are fully illustrated in van Engelen and Wen's SOTER manual (van Engelen and Wen, 1995).

The USLE was specially designed for erosion assessment at landscape level. For larger scales, like SOTER units, uniform slopes hardly occur and some places will be eroded whereas others will receive sediments. However, it can be used generally to compare regional erosion hazard classes (van den Berg, 1992). The basic equation of USLE is

$$A = R \times K \times LS \times C \times P \tag{30.2}$$

where

A is the soil erosion modulus

R is the rain erosivity factor

K is the soil erodibility factor

LS is the slope length and slope gradient factor

C is the vegetation factor

P is the engineering control factor

Figure 30.9 shows the result of the assessment. Water erosion risk in Hainan Island is low, and has a very low c value due to dense vegetation cover in the tropics. Slightly higher water erosion happens in the central mountainous region due to steep region slopes. However, given a little or no vegetation cover scenario, the erosion in this area would be extremely high (Zhao et al., 2003).

30.2.2.3 Land Suitability for Tropical Crops

The suitability of a crop depends on several major factors, namely, soil, site, and climate factors. Therefore, physical suitability

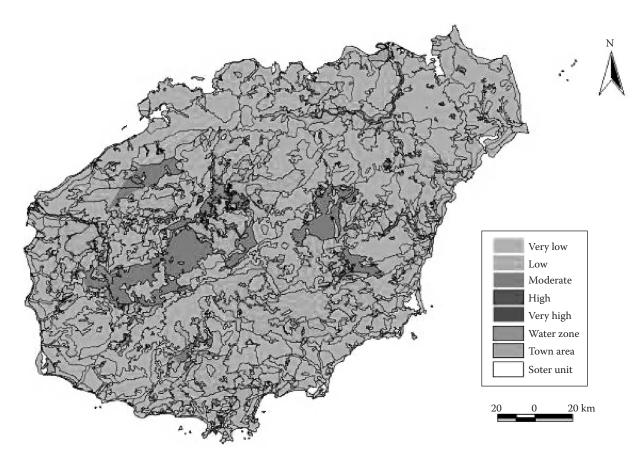

FIGURE 30.9 Soil water erosion risk of Hainan Island under current land use condition.

TABLE 30.2	Land (Dualities and Land	Characteristics	Used in the HAILES Model
-------------------	--------	--------------------	-----------------	--------------------------

Land Quality	Land Characteristics
Availability of moisture	Length of growing period (LGP), defined as $P > 0.5 ET0 + SM$; the period that rainfall (P) exceeds half the potential evapotranspiration (ET0) + soil moisture (SM) reserve, and temperatures are conducive to crop growth
Availability of nutrients	Soil reaction (pH), organic carbon, cation exchange capacity, base saturation percentage
Resistance to erosion	Slope, slope length, sol structure grade, sensitivity to capping/sealing
Flooding hazard	Frequency of flooding, flooding duration
Potential for mechanization	Slope, soil gravel content, surface rockiness
Availability of oxygen to roots	Soil drainage class
Soil toxicity	Aluminum saturation of the subsoil

assessment mainly considers these aspects. Crop suitability is also related to socioeconomic conditions; therefore, management at the input and technology level does matter (Mantel et al., 2003).

The framework for crop suitability assessment is set according to ALES (Rossiter, 1990). For land suitability assessment of tropical crops, such as banana, coffee, mango, and rubber, more specific grading systems were incorporated into HAILES (Mantel et al., 2003) Soil moisture condition, nutrient status, physical

status, site condition, and management levels were all considered as variables. Table 30.2 shows the major land characteristics used in the evaluation. Besides these factors, climate suitability (rainfall and accumulative temperature) was also divided according to the requirement of the crops.

Figure 30.10 is an example of such an assessment, which shows the classes of land suitability for rubber plantation in Hainan Island. A series of such maps were compiled, according

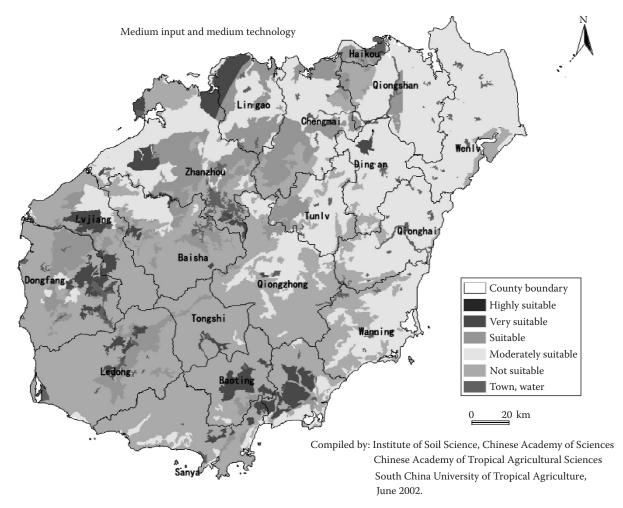

FIGURE 30.10 Rubber suitability in Hainan Island at medium input and technology level.

to different scenarios of management level, considering mainly chemical fertilizer input possibility and machine use potential (technology level).

The establishment of comprehensive soil databases is the base of modern land quality assessment. Up to now, several major databases are available for country and province level. At the local level, there are many more regional soil datasets. By comparing the newly sampled data with the original data, changes in soil properties and qualities can be monitored. Recently, the typical areas of major agricultural land were studied to determine the soil quality change in the lower Yangtze delta region, the low hill red soil region, the Huang-Huai-Hai plain region, and the northeast Mollisols region (Cao and Zhou, 2008).

30.2.3 Assessment of Land Degradation and Improvement in China

Land degradation is a global problem and a national issue in China. The Global Assessment of Land Degradation and Improvement (GLADA) under the LADA program indicates that over the last 25 years, 24% of the land surface has been degrading, in addition to the historical legacy of degradation since human settlement (Bai et al., 2008). In China, degradation of dry lands has received much attention and reclamation programs have achieved some success, but over the last 25 years, 23% of the country has suffered a decline of net primary productivity, 24% of the croplands and 40% of the forests, not mainly in

dry lands but in the high-rainfall areas of South China (Bai and Dent, 2008) (Figure 30.11).

GLADA analyses long-term trends in biomass productivity using remotely sensed NDVI data. The assumption is that these may indicate land degradation or improvement if false alarms due to climatic variability and land use change can be accounted for. In the preliminary analysis, climatic variability was taken into account by an analysis of rain-use efficiency and energy-use efficiency. Land use change, by itself, leads to changes in biomass that are not necessarily land degradation as normally understood. Recently, a study compiling NDVI changes, taking advantage of soil and terrain (SOTER) database of China, was conducted (Wu et al., 2010).

By overlaying land degradation results on a SOTER map, factors of land degradation can be analyzed. Comparison of degrading areas with land cover indicates that about half of the burnt, deciduous needle-leaved, evergreen broadleaved and mixed forests are all suffering degradation. Seventeen percent of cultivated and managed areas and about 34% of mosaic cropland are degrading. The most degraded land cover is grassland, occupying 31.1%; the second is needle-leaved forest, amounting to 19.3%; the third is cultivated land with 14.9% of the degrading land; the fourth is broadleaved forest, accounting for 14.2%; and just 4.8% of the degrading area is bare.

Of the improving area, 30% is cultivated and managed, 16.7% is mosaic cropland, 21% is grassland, and 16.8% is closed deciduous broadleaved forest. Cultivated and managed areas and herbaceous

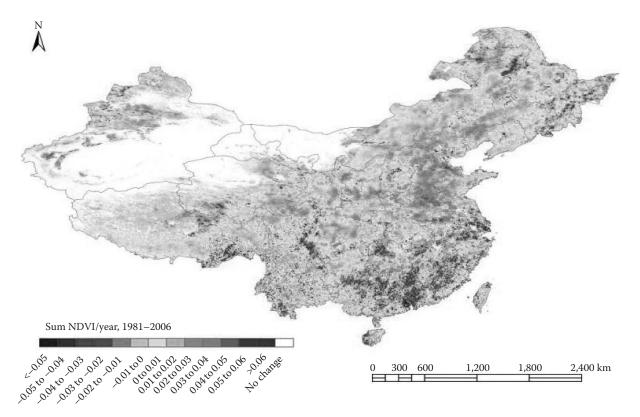

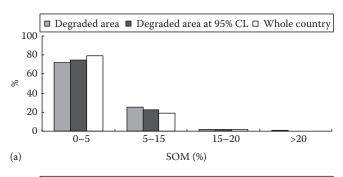

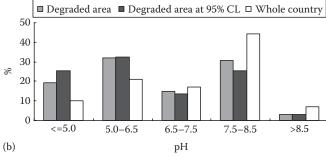

FIGURE 30.11 NDVI change of China over 1981-2006.

cover account for 63% of the whole improving area, which occupy 32.1% and 30.9% of the improving land respectively.

Relationships between soil properties and land degradation trends can be established too. Taking soil organic matter as an example, classes defined by 0%-5%, 5%-15%, 15%-20%, and >20%, occupy 72%, 25%, 2%, and 0% of the degrading area, respectively (and almost the same percentage of the degrading area at the 95% confidence level [CL]), similar to the national extent of each class (Figure 30.12a). There is almost no relationship between total soil organic matter and land degradation. The percentages of each pH class of degrading area are quite different from those of the whole country. With the decrease of pH, the percentage of each class of the degrading area or at 95% confidence level becomes bigger than that of the whole country, which shows the influence of lower pH on degrading land (Figure 30.12b). Clay classes are defined by 0%-15%, 15%-25%, 25%-45%, 45%-65%, and >65% based on international system of texture. The higher percentage of clay class 25%-45% of degrading area or at 95% confidence level compared with the whole country may show some tendency to degrade on this kind of texture (Figure 30.12c). In short, some soil attributes may influence land degradation.

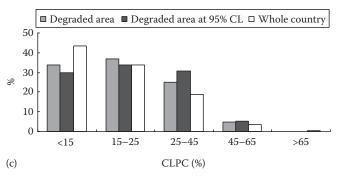

FIGURE 30.12 Area percentage of each class of soil attributes. (a, Soil organic matter [SOM]; b, pH; c, clay percentage [CLPC])

30.3 Future Development and Opportunities

30.3.1 Near-Future Tasks in Soil Correlation

Looking back at the history of soil mapping and soil database achievement, it is not difficult to draw the conclusion that for the vast agriculturally based country like China, soil information has been a prerequisite for any proper land management. However, the level of soil data acquired and manipulated are far from satisfactory.

First, the soil classification system has changed several times due to the influence of different academic schools in the world. It changed from the Marbut system, to Russian genetic system, and recently to the diagnostic system. It should be pointed out that soil classification has generally followed international trend, and the newly established taxonomic system does represent the current development of our knowledge. Influenced by soil classification, mapping legends changed as well. The legend systems and mapping scales for soil maps up to now have varied at different stages, which has led to problems in soil database construction, due to inconsistency and standardization problems with soil names, analytical methods, description standards, and so on. The new attempt to map the country at a small scale follows the new Chinese Soil Taxonomy and the corresponding legend system. For consistent soil database building, more correlation work must be done.

Second, the national soil maps usually adopt high soil classification categories as mapping legends, so the delineation of soil area is fairly heterogeneous. This is of course because of the size of the country, but it calls for a more detailed soil record. Similarly, the corresponding pedon data serving to explain soil delineations is not enough in terms of its adequacy to show the soil variability. A recent soil series inventory project, led by the Institute of Soil Science, Chinese Academy of Sciences, will hopefully provide many new and standardized datasets to update the original soil databases for various map scales. The new data will be precisely located with correct taxonomic names making it easy to pinpoint on a map. Such a soil correlation and inventory work will serve a better record of soil information and long-term application.

Third, the quality, standard, and interpretation of soil data need to be strengthened (Zhang et al., 2001b; Shi et al., 2007a). This is a huge task facing soil scientists. For a long time, there have been changes in soil survey terminology, analytical methods, soil classification, and so on. The data we have are not always comparable. This is, of course, an issue not only in China but in the international community as well. There is a pressing demand for soil scientists across the world to establish a real international standard. On the other hand, study of the models and expert systems applicable to soil data interpretation is fragmented in China. We may borrow some more or less universally used models elsewhere and modify them for use in China, but we also need to develop models that fit regional conditions in China.

Last but not the least, there is a room for the improvement of methods linking spatial data and attribute data. The currently used matching method normally takes the so-called central concept soil profile to represent the whole area and links the pedon data with the mapping unit. There is a high variation of soil properties within a certain area, as we know. The linking method of SOTER, which considers more than soil types, improves the precision of soil attribute data and spatial data matching, but remains with the similar problem of one pedon. How the spatial uncertainty can be reduced by linking and using multiple profile data is a work to be done.

30.3.2 Digital Soil Mapping and Its Practice in China

The need for more accurate, easy to use, and systematic soil information is increasing. Digital soil mapping (DSM) is an effort to provide high resolution rasterized soil data. It can be defined as "the creation and population of spatial soil information systems by numerical models inferring the spatial and temporal variations of soil types and soil properties from soil observation and knowledge and from related environmental variables" (Lagacherie and McBratney, 2007). The core of DSM is the soil–landscape relationship and its visualization through various models in the context of a geographical information system. Recently, many modeling methods have been tested in different locations. Scull et al. (2005) classified them into geostatistical, statistical, decision-tree, and expert system. Beside those, fuzzy logic method is also widely used (Zhu and Band, 1994; Zhu et al., 1996, 1997; Zhu, 1997a, 1997b).

Attempts to map soils digitally in China have also made some progress. By using geostatistical methods, Xu and Webster (1983) mapped soil nitrogen distribution in a county. Similarly, Wang et al. (2001) and Li et al. (2001) mapped soil thickness and soil water content by krigging, combining this method with remote sensing data. By establishing a linear regression relationship between soil properties and landscape parameters, Sun et al. (2008b) predicted soil organic carbon content in the low hill region of subtropical China and compared the impact of DEM resolution (Sun et al., 2008a). The decision-tree method was tested by Zhou et al. (2003, 2004) for soil property and type mapping in Zhejiang province. Sun et al. (personal communication) recently tried to map soils of Hong Kong by using decision-tree and discriminate analysis of various environmental covariates combinations, and found that the predicting models, rather than the covariate combinations, determined the preciseness of the final map. As fuzzy logic method is suggested to be very useful in predicting soil variation (McBratney et al., 1992; Moore et al., 1993; Zhu, 1997a, 1997b), much effort has been put into its use in soil mapping in China. Yang et al. (2007) and Zhao et al. (2007) used the fuzzy set of topographical data and conducted predictive soil property mapping based on soil-landscape relationships. Sun et al. (2008b) discussed the optimization of fuzzy clustering parameters.

There is an increasing belief that DSM will play a major role in the future. With the recent establishment of GlobalSoilMap.net, a global consortium has formed and pledges to contribute to the full coverage of high resolution rasterized soil data for the globe. It is believed that DSM will be soon put into the implementation stage (Lagacherie, 2008). The readily available technologies, including that of remote sensing, spatial database, spatial modeling, and so on, will promote the efficient acquisition of soil information. As an important participant of GlobalSoilMap.net, there are reasons to believe that China will develop in this direction too, following the international trend.

31.1 Introduction

Russia, the largest country in the world, encompasses nearly 30% of the world area of permafrost-affected soils, more than 60% of the world area of soils of the Boreal zone, and about 40% of the world area of Chernozems. More than a century since the shaping of modern pedology by V.V. Dokuchaev, Russian soil scientists have gained a vast amount of information about the soils of Russia. Some of the data are integrated in thematic information systems and databases, although a larger portion of it is preserved in paper form and cannot be readily applied in modern information technologies.

In the last decade, specialists from several organizations have digitized a great number of various thematic maps. In particular, the digital Soil Map of the Russian Federation on a scale of 1:2.5 M (1988) was developed, as well as a new digital map of the soil-ecological zoning (SEZ) of Russia on the same scale.

One of the major challenges facing Russian soil scientists is the creation of the national Soil Geographic Database (SGDB). The SGDB of Russia is considered a crucial element of soil inventory at the federal level. The SGDB should facilitate the regulation of land management and soil conservation policies in the country. The SGDB should be applied toward the development of legislative acts for soil protection and federal standards of soil quality for the purposes of soil-ecological monitoring. It should also serve as the basis for cadaster assessments of land resources

Work on the SGDB project was initiated by the Dokuchaev Soil Science Society in 2008 at the All-Russia Conference in Rostovon-Don. Since then, the concept and ideology of the project have been developed rigorously, and several major principles and goals of the SGDB have been formulated. The SGDB has been discussed in several papers and reports. The V.V. Dokuchaev Soil Science Society has presented soil scientists throughout the

country with a request to contribute their time and research to the development of the SGDB. Special software aimed to aid in the completion of the SGDB has been developed; work on filling out informational fields in the SGDB is still in progress.

31.2 Soil and Land Resources of Russia

31.2.1 Soil Resources

The total area of Russia is 17,098,242 km², extending nearly 3,000 km from north to south and nearly 7,000 km from west to east. These large dimensions allow for a diversity of environmental conditions throughout the country and many differences in land management practices. The environmental differences manifest themselves in different ways: from gradual geographic transitions to sharply pronounced contrasting changes.

The diversity of climatic and biotic conditions in Russia is the first group of factors determining the diversity of soils and soilscapes throughout the country. The second group of differentiating factors is related to the geological history of particular territories and their lithological composition; the chemical, mineralogical, and physical properties of surface deposits serving as parent materials; the hydrogeological conditions; and the modern dynamic processes shaping the surface topography.

The superposition of bioclimatic, litho-geomorphic, and historical-geological factors is responsible for the diversity and complexity of the soil cover in Russia.

General regularities of the soil cover of Russia and its regional differentiation are reflected in the most explicit form on the maps of SEZ.

The digital *Map of Soil-Ecological Zoning of Russia* (Figure 31.1, Table 31.1) was developed at the Faculty of Soil Science of Moscow State University on the basis of the *Soil Map of the Russian Federation* developed by the V.V. Dokuchaev Soil Science Institute under the supervision of V.M. Fridland (1988). SEZ is based on the taxonomic system with several hierarchical levels: (1) geographic belts and (2) soil-bioclimatic areas. These levels are further subdivided into mountainous and plain areas. Plain areas comprise (1) plain soil zones (subzones), (2) plain soil provinces, (3) plain soil regions, and (4) plain soil districts; and mountainous areas comprise (1) mountain soil provinces, (2) mountain soil regions, and (3) mountain soil subregions or mountain soil districts (not obligatory level).

The types of Russian soils are numerous, and extend from Arctic soils located on islands in the Arctic Ocean to Brown Semidesert soils of the Caspian Lowland, as well as Subtropical Yellow Ferrallitic soils from the foothills of the Caucasus in the south. Soils of the taiga zone occupy more than 50% of Russia, including Podzols and Gleyed Podzols (10.2%),

permafrost-affected Taiga and Gleyed Taiga soils (9%), Podburs (6.9%), Brown Taiga soils (2.8%), permafrost-affected Pale (Palevye) soils (3.1%), Gley-Podzolic and Podzolic soils (2.2%), Soddy-Podzolic soils (7.9%), and Bog-Podzolic and Peat Bog soils (11.8%). Smaller areas are occupied by Gray Forest soils (3%), Brown Forest soils (Burozems) (1.4%), Chernozems and Meadow-Chernozemic soils (7%), Chestnut (Kastanozemic), and Brown Semidesert Soils and their complexes with Solonetzes (3%). Mountain soil provinces occupy about one-third of the territory of Russia.

31.2.2 Land Resources

Land resources of Russia are classified with respect to land categories and land use types.

According to Article 7 of the Land Code of the Russian Federation (2001), seven land categories are specified in regard to land designation:

- 1. Agricultural lands
- 2. Settlement lands
- 3. Lands of industry, power generation, transport, communications, radio broadcasting, television, and information media; lands for ensuring spacecraft launches; lands of defense and security, and lands of other special designation
- 4. Lands of specially protected territories
- 5. Forest lands
- 6. Water-protection lands
- 7. Reserved lands

Data on the areas of different land categories in Russia for 2007 (Rosnedvizhimost', 2008) are given in Table 31.2. A majority of the country (about 65%) is classified as forest land. Agricultural

TABLE 31.2 Distribution of Russian Lands by Land Use Categories (as of January 1, 2008)

Land Category	Thousand Hectares	Percentage of the Total Area
Agricultural lands	403177.0	23.58
Settlement lands	19258.5	1.13
Lands of industry, electric power, transport, communications, radio broadcasting, television, and information and lands for ensuring outer space activity, lands of defense and security, and lands of other special designation	16687.4	0.98
Lands of specially protected territories and objects	34393.8	2.01
Forest lands	1104975.9	64.62
Water-protective lands	27942.3	1.63
Reserved lands	103389.3	6.05
Total	1709824.2	100

Source: Data from Rosnedvizhimost. 2008. National report on the state and use of land in the Russian Federation in 2007. Federal Cadaster Center, Moscow, Russia [in Russian].

lands occupy more than 23% of Russia's territory, while specially protected territories occupy 2% of the area of Russia.

Land use type is defined as an area regularly used for specific economic purposes and having specific natural, historical, and other properties. In accordance with current economic use, all the lands are subdivided into two major groups: (1) agricultural lands, that is, lands actually or potentially used for agricultural production, and (2) nonagricultural lands, that is, other lands not used in agriculture.

Agricultural lands include the following land use types:

- 1. Plowland
- 2. Idle land (fallow, temporarily abandoned land)
- 3. Perennial plantation
- 4. Hayfield
- 5. Rangeland (pasture)

Nonagricultural lands are subdivided into the following land use types:

- 1. Land subjected to reclamation measures
- 2. Land under forest
- 3. Land under woody-shrub vegetation
- 4. Land under water bodies
- 5. Land under bogs
- 6. Land under construction
- 7. Land under roads
- 8. Disturbed land
- 9. Other lands

Data on land use in Russia (as on January 1, 2008) are given in Table 31.3.

Only about 13% of the country is actually used for agriculture (land use types 1–5). More than 50% is considered forest land. Other lands not used for agricultural purposes compose

TABLE 31.3 Distribution of Russian Lands by Land Use Types (as of January 1, 2008)

Land Type	Thousand Hectares	Percentage of the Total Area
Agricultural lands, including	220567.9	12.90
Plowlands	121573.5	
Fallow	5105.7	
Perennial plantations	1794.2	
Hayfields	24004.1	
Pastures	68090.4	
Forest lands	870761.2	50.93
Forests beyond the category of forest lands	26594.5	1.56
Lands under water	72049.8	4.21
Lands under construction	5604.9	0.33
Lands under roads	7937.8	0.46
Bogs	152936.9	8.94
Disturbed lands	1107.5	0.07
Other lands	352263.7	20.60
Total	1709824.2	100

one-fifth of the total land reserve. These are mainly glaciers; lands occupied by landslides, slumps, and ravines; tundras; windblown sands; landfills; and dumps.

Table 31.4 contains data on the percentage of major soil types in the total agricultural, as well as the plow land of Russia.

Nearly 75% of Russia lies in the cold zone and in the mountainous regions with an insufficient heat supply. Only focal crop farming is possible in these areas. Rangelands are also limited in these regions.

A combination of sufficient heat supply (with the accumulated mean daily temperatures above 10°C of more than 2500 degree days) and sufficient moistening (with the precipitation to

the potential evapotranspiration ratio of more than 0.75) is only observed on about 1% of Russian land.

Territories with optimum combinations of high heat supply and sufficient moisture are virtually absent in Russia.

31.3 History of Collection of Soil Information in Russia

31.3.1 History of Soil Mapping

Soil mapping in Russia has a long history. The first estimates of soil resources were based on the written descriptions of real estate prepared by local officials in the time of Ivan the Terrible in the sixteenth century. The first soil map of European Russia on a scale of 1:8 400,000 was compiled and edited by academician N.S. Veselovsky on the basis of information sent by local land committees; it was published in the *Economic-Statistical Atlas of European Russia* in 1851. Despite the schematic character of this map, its publication was a noteworthy milestone in the study of soil resources of the country.

In 1879, a new soil map of European Russia on a scale of 1:2,520,000 was published. This map was developed by a statistician V.I. Chaslavsky on the basis of completed questionnaires received from local land committees. After the death of Chaslavsky, V.V. Dokuchaev was entrusted with the preparation of explanatory notes to this map. They were published in 1879 under the title *The Cartography of Russian Soils*. In this work, the basic principles of pedology and soil cartography were outlined by Dokuchaev for the first time. Field studies on land assessment for a "better justified taxation" were performed by Dokuchaev and his team in the 1880s and 1890s. With other special soil survey works, they served as the basis for the first soil map of European Russia based on factual results of soil surveys and compiled on a scale of 1:2,520,000 by N.M. Sibirtsev, G.I. Tanfil'ev, and A.R. Ferkhmin under the supervision of V.V. Dokuchaev in 1900.

A new period in the study of soil resources began in the 1920s. Large-scale soil surveys of agricultural territories were organized with the aim of providing the cartographic basis for rational land use planning, crop rotation, agrochemical service, and soil reclamation.

The scales of Russian soil maps are subdivided into detailed (1:5000 and larger), large-scale (1:10,000–1:50,000), medium-scale (1:100,000–1:300,000), small-scale (1:500,000–1:1,000,000), and general (smaller than 1:1 M) maps.

Detailed soil maps have been developed for experimental fields and strain-testing stations. Large-scale soil maps are compiled for land use planning and land reclamation purposes at the level of particular farms, while medium-scale (sometimes, large-scale) soil maps are used for agricultural and forestry planning at the levels of administrative districts, oblasts, and regions. Small-scale and general soil maps are used for strategic economic planning at the federal level as well as for educational purposes. Soil maps of different scales are used to assess soil resources and land quality, and to perform soil zoning for various applied and scientific purposes.

Since the 1960s, the data provided by aerial surveys and satellite imagery have been applied to large-scale soil mapping. Their application has made it possible to improve the accuracy and objectivity of mapping large areas of soil. Large-scale soil maps, developed by local research institutes for land surveys and land management, have been supplied with explanatory notes containing the descriptions of representative soil pits, analytical data on the soil properties, and recommendations on the optimum use of soil resources. By the 1990s, three to four rounds of large-scale soil surveys were performed for agricultural lands of Russia.

In the 1970s and 1980s, zonal institutes for land management and land planning initiated the work of compiling mediumscale soil maps for the administrative regions and oblasts of Russia. These maps were developed based on large-scale soil maps. In some cases, new remotely sensed data were used for their compilation. The legends to these maps are rather detailed (normally about 150 mapping units are shown on them). Inset maps show the agricultural zoning of the territory as well as soil erosion and other hazardous processes. In general, the degree of detail on such maps is much higher than that on mediumscale soil maps developed in the first half of the twentieth century. Recently, a new methodology for compiling medium-scale soil maps with the use of GIS technologies has been prepared by the V.V. Dokuchaev Soil Science Institute (Simakova, 2008). Regional soil maps on the scales of 1:50,000-1:100,000 have also been developed by various research institutes for about a half of the administrative regions of Russia (Simakova and Andronikov, 1999). Unfortunately, most of them have not been published and are stored in various archives.

The accumulated data have also been generalized in a series of general soil maps. These maps include the Soil Map of the Soviet Union (1:4 M) developed by N.N. Rozov and E.V. Lobova with I.P. Gerasimov as editor in 1954, soil maps included in the Physico-Geographic Atlas of the World (Ed. I.P. Gerasimov, 1964), Soil Map of the World (1:15 M) developed by Glazovskaya and Fridland (1982), and others.

In the 1930s, L.I. Prasolov initiated the development of the State Soil Map of the Soviet Union on a scale of 1:1 M. This work was resumed in 1949. Presently, this is the most detailed soil map for the entire territory occupied by Russia and the FSU countries, as well as the main reference for assessing soil resources at the federal level. This map developed by the V.V. Dokuchaev Soil Science Institute synthesizes knowledge on the genesis and geography of soils gained by Russian pedologists in the second half of the twentieth century.

In the past 60 years, 111 separate pages of this map have been published. They encompass the territory of all the republics of the former Soviet Union. For Russia, 83 pages of this map have been published, mainly for the agricultural regions. The total list of soils and soil complexes shown on separate map pages exceeds 1000 mapping units. The work on unification of the legend to the map and harmonization of separate pages is in progress.

In 1988, the Soil Map of the Russian Soviet Federal Socialist Republic (*Soil Map of the Russian Federation*) on a scale of 1:2.5 M,

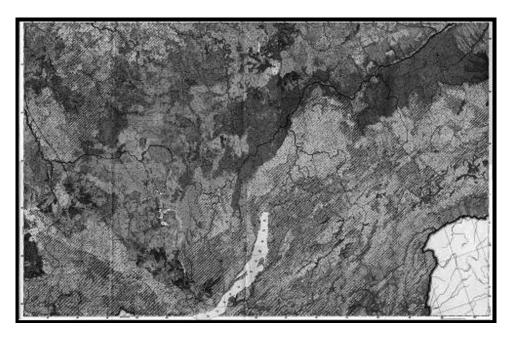

FIGURE 31.2 (See color insert.) Soil map of the Russian Federation.

was published. This map was created in the V.V. Dokuchaev Soil Science Institute on the basis of data provided by a large team of scientists from various research and educational institutes in Russia. This project was carried out under the supervision of V.M. Fridland. It consists of 16 pages (Figure 31.2) and presents the most detailed information on the soil cover of the entire Russia in published form.

In the 1960s and 1970s, important work on the generalization of soil maps and the development of soil geographic and soil-agrochemical zoning maps was performed. The Soil Geographic Zoning of the Soviet Union (1962), Soil-Agricultural Zoning of the Soviet Union (1975), the Soil-Agrochemical Zoning of the Soviet Union (1976), the Map of Soil Geographic Zoning of the Soviet Union (1983), and the recently developed digital Map of Soil-Ecological Zoning of Russia (edited by Dobrovol'skii and Urusevskaya (2007)) are the major accomplishments of this effort.

31.3.2 History of Soil Information Science and the Development of Digital Soil Mapping in Russia

The application of modern informational tools to soil studies began in the 1970s, with the appearance of the first data banks and their structural and functional components (databases) (Rozhkov, 2002). By that time, mathematical methods had actively been applied by soil scientists and agrochemists. Data archives on notched cards became prototypes of data banks (Fridland and Il'ina, 1972). The first steps in the development of information technology in soil science (or soil informatics as referred to by B.G. Rozanov) were made at the V.V. Dokuchaev Soil Science Institute.

In 1980, a complete system of soil classification and coding (SCC) was created. The final description contained five volumes

and included all known soil characteristics and methods of their determination, a classification table, and the forms of data input. Being a formalized language of soil description, this system was designed for the development of a national bank of soil data with the application of a commercial system of database management INES for ES-1020 computers. This language was used in the creation of the Automated Information Search System (AISS) SOIL.

In order to improve the classification system, its basic principles with abbreviated forms for soil description and with a system of data coding were published (Rozhkov et al., 1982). Later on, the concept of the information base of soil classification was suggested (Shishov et al., 1985), and a special *Guide to Soil Description in the Soil Classification Database System* was published (Shishov, 1986). In accordance with the suggested descriptive structure, the information system MERON with formalized descriptions of individual soil types was created (Rozhkov and Stolbovoi, 1988).

By the early 1990s, several information systems and separate databases were developed by the V.V. Dokuchaev Soil Science Institute. With these as a base, the bank of soil fertility models was created (Frid, 1999).

In the 1990s, work on applying geographic information systems to soil science was initiated by the V.V. Dokuchaev Soil Science Institute using EPPL7 (U.S.) software. An original GIS envelope called LESSA was developed by V.B. Vagner. Based on LESSA, and with the support of the Russian Foundation for Basic Research, the first bank of maps and their related attribute databases was shaped. In 4 years, an ecological soil atlas was developed in the GIS environment.

In 1995, the Dokuchaev Soil Science Institute purchased the world-standard program ARC/INFO and the Digital Chart of the World (DCW) (1:1 M) showing relief, hydrographic network,

and infrastructures. The Soil Map of the Russian Federation and the Landscape Map of the Soviet Union (1:2.5 M scale) were some of the first to be digitized. Thus, the first serious soil GIS at the federal level appeared. The attribute databases of these maps are being updated constantly. The cartographic base of the Dokuchaev Soil Science Institute was registered in the international network GRID UNEP. Information on some of the maps developed by the institute can be found on the Web site http://agro.geonet.ru.

Representatives of the V.V. Dokuchaev Soil Science Institute (V.S. Stolbovoi and E.N. Rudneva) participated in the international project on the Global Assessment of Human-Induced Soil Degradation (GLASOD). This work was continued from 1997 to 2000 within the framework of the Soil and Terrain Vulnerability in Central and East Europe (SOVEUR) project aimed at the creation of GIS for the assessment and prognostic modeling of different types of soil degradation in this vast region.

An important issue was the integration of the Russian soil classification system into the soil database of the European Community (Stolbovoi et al., 2001). This step was intended to facilitate the creation of a unified policy regarding land use and soil monitoring. Russian classification was linked to the World Reference Base on Soil Resources. The soil map of Russia was also interpreted in terms of the FAO legend to the Soil Map of the World. The Dokuchaev Soil Science Institute suggested that the World Reference Database for Soil Resources should be organized as an information system in 1990.

Active work on the creation of new digital maps, as well as the use of cartographic and statistical databases for the assessment of soil resources, is being performed by the Faculty of Soil Science and by the Institute of Ecological Soil Science of Moscow State University. Soil maps of Russia on the scales of 1:25 M, 1:22 M, and 1:15 M and a digital version of the Map of Soil Ecological Zoning of Russia on a scale of 1:2.5 M have been developed.

The geographic information system has been created using the MapInfo format; it includes differently scaled maps for the entire territory as well as for separate regions of Russia. Some of the initial sources of cartographic information used in this work were published materials, unpublished original materials, and specially purchased digitized maps. Some of the digitized cartographic materials available on different scales for the entire territory of Russia are listed in Table 31.5.

In recent years, geographic information systems have been extensively applied in Russian agriculture. Since 2006, the Computing Center of the Ministry of Agriculture has been involved in the development of a remote-sensing system for the monitoring of agricultural lands. This system's objective is to integrate previously accumulated archive data and recently obtained data to refine the inventory of agricultural lands, to evaluate the efficiency of their use, and to predict crop yields. This system includes the federal and regional geographic information systems arranged according to the hierarchical principle: from the federal level to the level of local farms (specially selected representative farms) and fields. This process is based on digitized cartographic data in the ArcGIS format and satellite imagery subjected to continuous renewal (http://www.gisa.ru/pd_1_09.html).

31.4 Soil Geographic Database of Russia

The development of the SGDB of Russia is aimed at providing the scientific basis for the federal strategy of sustainable land use, soil monitoring, and soil conservation (Shoba et al., 2008).

Thus, the major objectives of the SGDB are as follows:

- The inventory and formalization of data on Russian soils.
 Most information on soil profiles is presently kept as hard
 copies—published articles, monographs, collections of
 papers, dissertations, and field records. These data should
 be unified and prepared for collective use.
- Information support of research projects and educational programs.
- The integration of Russia into a unified soil-information space of the European Community and the world and in various global and regional soil programs.

The main principles of SGDB development and functioning are as follows:

- The integration of soil information is based on digital maps using modern GIS technologies.
- The base map scale is 1:2.5 M. This scale is selected because
 this is the largest scale of digitized soil map for the entire
 country developed on the basis of a unified legend and
 common methodological principles.
- Openness of the database and the possibility for its further augmentation.
- Availability of the database.
- Involvement of a wide range of specialists in soil science and related disciplines possessing original information on the morphological and physicochemical properties of representative georeferenced soil profiles to be included in the SGDB.
- Online data transfer via the Internet.
- Offline administration and edition of input materials (for ensuring data security and quality).
- Involvement of experts in the work with input materials from separate contributors.

The main blocks of the SGDB are the Geographic Database and the Specialized Attribute Database. A relational database management system is used for data storage and processing.

31.4.1 Cartographic Block: Digital Maps

The cartographic base of the SGDB—the Geographic Information Soil Database—consists of two digitized maps in the MapInfo format. COVERAGE 1 is a digital map uniting the Soil Map of the Russian Federation on a scale of 1:2.5 M edited by V.M. Fridland (1988) (corrected digital version, 2007) and the Map of Soil-Ecological Zoning of Russia on the same scale edited by Dobrovol'skii and Urusevskaya (2007). COVERAGE 2 is the digital map of the administrative division of Russia on a scale of 1:1 M (2007).

31.4.1.1 Soil Map of the Russian Federation, 1:2.5 M Scale

The digital version of this map consists of 25,711 polygons (soil delineations). Each polygon contains information on the soil cover (color) and parent materials (hatching). The legend to the digitized map includes 200 names of individual soil units, 70 names of different soil complexes, 5 names for nonsoil formations, and 30 legend units for textural classes and petrographic composition (for hard rocks) of soil parent materials. Correlation of the Legend to the Soil Map of the Russian Federation with international and foreign soil classification systems can be found in Fridland (1982), Shishov et al. (1985), Rozhkov et al. (1990), Stolbovoi and Sheremet (2000), and CD-ROM Land Resources of Russia (2002).

A given polygon may include up to four soil units (or soil complexes). The main soil (soil complex) unit occupies 100% of the polygon area in the absence of accompanying soils (complexes), 75% in the presence of one accompanying soil (complex), 65% in the presence of two accompanying soils (complexes), and 55% in the presence of three accompanying soils (complexes). The accompanying soils are considered to occupy equal areas. In soil complexes, the percentages of component soils are not calculated. Parent materials in soil polygons may be represented by one (major) or two (major and accompanying) units.

31.4.1.2 Digital Map of Soil-Ecological Zoning of Russia, 1:2.5 M Scale

In the digital map of SEZ, 1377 polygons are separated (Figure 31.3).

The digital version of this map contains information about soil cover and the factors of its differentiation at different levels. Thus, at the soil district level, information about soils and their texture is given; at the soil region level, information about the genetic types of relief, parent materials, land use pattern, and soil quality classes is provided. For larger typological units—soil provinces—parameters of atmospheric and soil regimes are given for plain territories and the patterns of the vertical soil zonality are indicated for mountainous territories.

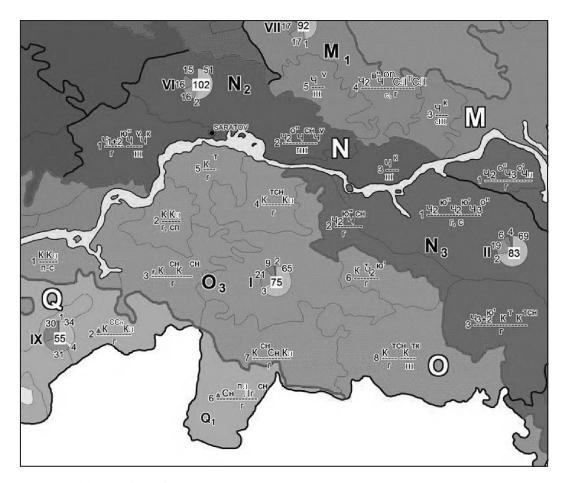

FIGURE 31.3 Fragment of the map of SEZ of Russia.

31.4.1.3 Soil Map Combined with the Map of Soil-Ecological Zoning of Russia, 1:2.5 M Scale: COVERAGE 1

Digitized versions of the soil map and the map of SEZ on a scale of 1:2.5 M are combined into COVERAGE 1. The number of polygons on this integral map reaches 32,605. Each polygon contains information from both maps (Table 31.6).

31.4.1.4 Digital Scheme of the Administrative Division of the Russian Federation, 1:1 M Scale: COVERAGE 2

At present, there are 83 subjects of the Russian Federation, including oblasts, krais (regions), republics, autonomous areas, autonomous oblast, and two cities. They are combined into eight federal okrugs: Tsentral'nyi (Central), Severo-zapadnyi (Northwestern), Yuzhnyi (Southern), Severo-Kavkazskii (North Caucasian), Privolzhskii (Volga), Ural'skii (Ural), Sibirskii (Siberian), and Dal'nevostochnyi (Far Eastern) (Figure 31.4).

COVERAGE 2 includes 2394 polygons representing the administrative division of Russia. It contains data of the

Federal Statistical Survey of land resources performed by the Federal Agency for Realty Cadaster for January 1, 2006 (Table 31.7).

31.4.1.5 Additional Digital Cartographic Materials

Currently, work on inclusion of additional materials in the geographic database is being performed. In particular, these are characteristics of relief and parameters of soil temperature regimes.

Digital elevation model (DEM) with a horizontal grid spacing of 30 as (approximately 1 km) is taken from the Land Resources of Russia CD-ROM (2002).

Long-term soil temperature data (Table 31.8) recorded at 370 weather stations in 1960–2000 were provided for the database by D.A. Gilichinskii (the Laboratory of Cryogenic Soils, Institute of Physicochemical and Biological Problems of Soil Science, Russian Academy of Sciences, Pushchino).

The large volume of information concerning soils, their properties, functions, soil factors of soil formation, soil cover patterns, and land use is also available from digitized maps on different scales included in the GIS of Russia (Table 31.5).

31.4.2 Attribute Block: Soil Profile Database

31.4.2.1 Contents and Structure of Soil Profile Database

The database of representative soil profiles is an attribute part of the SGDB. Representative soil profiles should be provided with information on their geographical location and with a complete set of data on soil morphology and analytic properties to be included in the database.

The main component of the SGDB database is a soil profile with a set of soil horizons characterized by attribute data. Necessary information on the properties and composition of soils is obtained via selecting of representative soil profiles characterizing the main soil types shown on the Soil Map of the Russian Federation (1:2.5 M scale). A series of representative soil profiles for a given soil type makes it possible to calculate averaged characteristics for this soil type. Information on the regional features of soil cover patterns, vegetation and relief conditions, soil-forming rocks, and climatic parameters is taken from the Geographical Database.

The systematization of data on the selected reference soil profiles implies a unified form of data presentation. For this purpose, classifiers (systematized lists of parameters) were developed based on existing concepts of soil morphology and basic scales used in the current descriptions of soil profiles. The form and format of data presentation are described in detail in the attachment to the database. The necessity for including both the results of recent studies and the vast archival materials into the database is taken into consideration. Most soil attributes are ranked using specially developed scales (the database envisages the description of each attribute and its range). The developed systematized list of parameters includes two large sections:

- 1. Parameters characterizing the location of soil profiles and the morphological characteristics of soils
- 2. Parameters characterizing the physical, chemical, physicochemical, and other soil properties

The database has a hierarchical structure ensuring soil description at several levels: SOIL-PIT-PROFILE-HORIZON-SAMPLE (Table 31.9).

The set of semantic soil data is given in Table 31.10.

At the SOIL level, the classification position of the soil is given. For the purposes of correlation between the existing classifications, the most complete descriptions of soils are given within the frameworks of current national and world soil classification systems.

The description of a pit includes the characterization of the pit site, the main factors of soil formation (including relief, parent materials, and vegetation), and the source of information. The number of genetic horizons, the degree of disturbance of the profile, and its genetic type are also indicated. The HORIZON level includes a description of the most common morphological properties of the horizons, as well as the description of soil morphological elements at the next hierarchical level.

At the SAMPLE level, data on the physicochemical properties of soils are systematized. In this section, the values of the

31.4.2.2 Soil-DB: Software for Filling in the **Attribute Database on Soil Profiles**

A special software, Soil-DB (version 1.0) has been developed for database management (Alyabina et al., 2009). This software is intended for the input of initial soil information by contributors to the SGDB and transmission to the central server of the system, where the collective SGDB is being created. Information on the SGDB, User's manual, and the Soil-DB software are available from the Web site http://db.soil.msu.ru.

Development of the system includes several stages. The first stage is registration of potential contributors. Registered contributors may fill in the cards of soil description using the suggested software tools and send these cards to the central server of the system via the internet. At the next stage, moderators of the system verify information received from the particular contributors and decide (with the help of experts) on the feasibility of its inclusion in the SGDB. The contributors are informed of this decision. In certain cases, not all the fields of the card concerning the classification position of the soil and its exact geographic coordinates are filled in by the contributor. These fields may be filled in by experts who link information about soil profiles to the geographic database.

The Soil-DB program, together with tens of built-in information lists, is rather compact and occupies less than $500\,\mathrm{Kb}$ of disc space. The files created with the use of this program are also small (2–3 Kb). This allows one to keep and launch the program from a flash card.

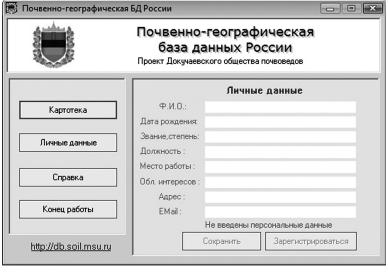

Filling in of Personal Data and Registration in the System

To register in the system, the registration form should be filled in (Figure 31.5a). Three fields of this form are obligatory for registration: (1) personal data (name/family name), (2) address, and (3) email. This information is necessary for contact between moderators of the database and the registered contributors, and is confidential. Registered persons acquire the status of official participants to the project and may contribute to the collective database. A participant may fill in the cards for soil description and send them to the central server of the system to supplement the database.

Information Units

The major information unit of the Soil-DB program is a card with the description of a given soil horizon (sample). Numerous separate cards can be organized by a user of the system into a card file. Any card can be supplemented and/or edited at any time by saving the results on the system. Because a considerable volume of information is in separate cards, it is subdivided into separate pages (thematic fragments) on the monitor. A transition from any given card to another card is accomplished with the help of a menu bar, from which necessary page names can be selected. Each page contains several rubricated fields represented either by a menu from which necessary items can be selected, or a window, in which necessary textual or numerical information can be filled in. Many ways of completing the fields are available in the program: keyboard typing, copy-paste procedure, choice from the list of variants (including multistep lists), and the input of nonformalized data that do not fit the developed data structure.

Pull-down menus are the main means of data input; these menus contain necessary lists of classifiers of soil properties, so that a user can select required information from the menu window without typing it. This approach makes the completion of the cards more efficient and allows one to avoid typing errors. There are simple and complex (hierarchical) pull-down menus. In a simple menu, only one window for the choice of appropriate information is opened. In a complex menu, two or three windows with hierarchically organized information lists are opened. Complex menus differ from simple menus in the font color and background color. The left panel (red font) is used to select the appropriate term for a general description of the macrorelief (e.g., plain territories), and the right panel (white font against blue background color) is used to specify the description (alluvial and ancient alluvial plains).

(a

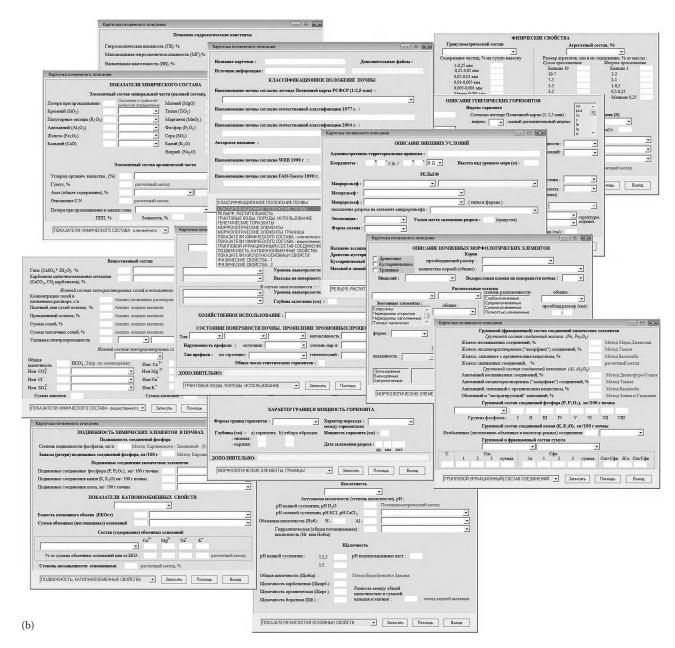

FIGURE 31.5 (continued) (b) Pages of the card file.

In some cases, several entries from the menu can be selected. For this purpose, multiple-selection menus are suggested. They consist of three–four visible information lines against the pink-colored background. Most of these menus have scroll bars allowing the selection of appropriate information.

In a blank (new) card, all the pull-down menus are initially empty (nothing is selected). If the required information for a given menu is absent, its window should be left empty. Upon the submission of the completed card to the central database, such empty windows are considered as a lack of data (no data). Upon the secondary opening of the earlier filled card, previously selected information is shown in all the menu fields. It can be changed at any time, and the last choice will be saved on the disk and opened during the next opening of the card.

Textual Fields

Some of the windows opened on card pages are designed for the entry of textual information (names, descriptions, etc.). Where necessary, the maximum length of the text is limited, though such limits are absent in most cases.

Numerical Fields

The windows designed for the entry of *integers* have certain limits for the number of digits. These limits are set up in order to avoid unfortunate misprints and errors because of the inadvertency of the users. With the same aim, only digits can be inserted into such windows; letters and symbols are not allowed. The windows designed for the entry of *fractional numbers* (e.g., for

the values of some physical and chemical soil properties) do not have special limitations for the number of digits and for their format. However, only digits and the decimal sign (period) can be inserted into such windows.

Card Maintenance and Transmitting to the Server

After the launch of the program, a panel of the most frequently used (default) regime of card filling is opened. To begin the work, the blank card has to be created and saved as a file. Each card is a separate file stored in the same directory as the Soil-DB program.

The program ensures the following options for the work with the cards:

Card editing (menu bar "Edit"). After pressing this bar, a panel for data entry and editing of information is opened.

Card copying (menu bar "Copy"). A copy of the selected card is saved under another name. This option is useful upon the availability of analytical results in several duplicate cards, for the description of different horizons in the same soil profile, or for the description of several soil profiles within the same area, (for which a larger part of the information is identical, and only several information fields are different). In such cases, a copy of the first card is made, and then information in necessary fields is changed.

Menu bar "Delete" is used to delete unnecessary cards.

Menu bar "Send to the Database" is used for sending the card to the central server and to the moderator of this work. After the card is verified by the moderator, its information becomes available from the collective database.

Each soil profile's geographic location should be indicated. Coordinates of the pit (longitude and latitude) are given, and the radius of uncertainty (in meters or kilometers) should also be indicated. In case such information is unavailable (for archive data, literature sources, dissertations, etc.), approximate location in relation to a nearby settlement or other notable geographic feature is acceptable (e.g., 2 km to the northwest from Peskovka railway station).

The multipage format of the card assumes that not all the fields are obligatory. Some fields may remain empty in the case of missing corresponding information. Overall, the card consists of 13 pages (Figure 31.5b). The first six pages are designed for the description of the classification position of a soil, the environmental conditions in the area of described soil profile, and the soil morphology.

Pages 7–13 are designed for the description of soil chemical and physicochemical properties. For each characteristic, special fields for the numerical values of particular properties, measurement units, and the methods of their determination (to be selected from the pull-down menu) are provided.

The program also suggests fields for the input of nonformalized data. Thus, the "Additional Files" field on the first page of the soil profile description is used to indicate the names of files sent to the moderator of the system with the descriptions of

soil attributes that are not included in the standard list. Also, each page of the standard soil descriptions ends with the line "Additional Information" against the yellow background color. This line should be filled in with any relevant information about the particular soil and not included in standard menus.

31.4.2.3 Development of the Attribute Database on Soil Profiles

The development of an attribute database on soil profiles was initiated by specialists from the Dokuchaev Soil Science Institute. Appropriate data are derived from published and archived sources, including the archive of dissertations at the Higher Attestation Commission of the Russian Federation. Representative soil profiles characterizing the soil cover of Russia are typically selected. An obligatory requirement to the data sources is the exact knowledge of the geographic position of a given soil profile, or its allocation to a given delineation on the Soil Map of the Russian Federation (1:2.5 M scale). The selected profile should also have a full morphological description and be supplied with analytical data on the main physical, physicochemical, and chemical properties. The quality and completeness of these data are assessed by the experts.

Currently, the National Soil-Geographic Database of Russia includes data on 584 representative soil profiles with nearly 3000 samples from the genetic soil horizons.

Additionally, data on 688 representative soil profiles on the European part of Russia have been selected. At present, an expert evaluation of these data is performed, and the classification position of corresponding soils is verified. After completion of this work, this data will also be included in the Soil-Geographic Database. The search of representative soil profiles for the Asian part of Russia is still in progress.

31.4.3 Software Support of the SGDB

Work on filling in the SGDB is performed using cartographic data presented in the MapInfo format (MapInfo Professional, version 9.5 and earlier versions) and with attribute soil data in the Microsoft Office 2007 format; the database management on the server is ensured by the PHP, MySQL, and MapServer software (Windows platform).

The SGDB management will be ensured by several programs.

- Software for the local input of soil data (Soil-DB)
- Modulus of information input–output on the server
- Relational database management system on the server
- Program for administrating, editing, and conversion of the input information (TXT-format) into the format designed for storage and transfer of structured data (XML-format)
- Modulus of remote database query (search for necessary data from metadata) and data output via internet

At present, the first two software tools are ready. The third and fourth software tools are being developed. The work on database

query software is at the stage of selection of the particular indices to be displayed on key fields.

Technical documentation to the program with a detailed description of the work of the system and with an instruction for filling in soil description cards can be obtained from the website devoted to the SGDB of Russia (http://db.soil.msu.ru).

31.5 Conclusions

At present, one of the challenges for Russian soil scientists is to ensure the legal status of soil as a natural resource via the preparation of the corresponding legislative act for its adoption by federal authorities. In this context, the inventory of soils of the country and the creation of the All-Russia SGDB as the scientific and information basis for the policy of sustainable land management are necessary. A computer-based inventory of extensive soil information linked with digitized soil maps and the use of modern GIS technologies will make it possible to create this database and to apply it for soil monitoring purposes and for the development of a unified system of soil management, certification, and conservation.

The development of the collective SGDB as an available information center for collecting, storage, and processing of soil information is in progress. This work is performed by specialists in soil science and related sciences. The SGDB of Russia should be compatible with the European Soil Database and the World Reference Base for Soil Resources. This will make it possible for Russian soil scientists to be integrated into the common European soil information system and to participate in the development of global soil programs.

Acknowledgments

This chapter summarizes the work of many people. The authors are particularly grateful to academician G.V. Dobrovol'skii for his moral support and valuable consultations; to Professor of the Department of Soil Chemistry of Moscow State University L.A. Vorob'eva, who developed the conceptual scheme of the database on the chemical properties of soils; and to program engineer V.V. Artyukhov, who contributed to the development of the software support of the SGDB of Russia.

32.1 Introduction

Africa has long been known as the "Dark Continent," due to such factors as the difficulties posed by travel across its unforgiving terrain. Even today, in the twenty-first century, because this situation persists in places, it has been said that more is known about the soils on the Moon or Mars than many parts of Africa. The colonization factor in Africa is well-known, but one of its consequences was that when a need for increased characterization and cataloguing of the natural resources of the various countries on the continent arose in the mid-twentieth century, these tasks were carried out largely by colonial powers or their representatives.

The main result of this was that, with few exceptions, soil maps and other data concerning the natural resources of Africa were collected and stored outside the continent and became difficult to trace and inventory. However, because there is now a much greater spirit of cooperation between both African countries and their former colonial (mainly European) partners, much of the information has been, or is currently being, incorporated into robust and readily available source databases.

32.2 Background

Africa covers an area of just over 30 million km² and has a population of 877 million, second only to Asia. The continent comprises 53 countries, with the largest in area being Sudan (2.505 million km²) and in population being Nigeria (149 million). The level of development varies greatly, being limited by topographical features such as the Sahara desert and the Congo River basin but being driven by the occurrence of mineral or other resources, which provided the incentive for early development, such as the gold and diamonds in South Africa, copper in Zambia, and, at a later stage, oil and gas in Nigeria.

32.3 Soil Characterization

About half of all the world's "tropical soils" lie in Africa and are associated with unique features such as high rainfall, warm to hot temperatures, intense weathering, and rapid leaching, to name but a few. These soils thus present significant challenges to those wishing to utilize them for food and fiber production.

Although the first soil survey was carried out in Madagascar in the late 1890s (van Ranst and Verdoodt, 2010) and several surveys of smaller areas, such as irrigation schemes in South Africa, were carried out in the 1920s and 1930s (MacVicar, 1980), the first significant studies of African soils originated from Russia (Schokalskaya, 1944) and America (Shantz and Marbut, 1923), both at scales of approximately 1:30 million. The first real impetus to improve on these maps came from the Inter-African Pedological Service, under the leadership of J.L. d'Hoore, which recommended production of a map at 1:5 million. The first edition of this map was produced in 1964 (d'Hoore, 1964), reflecting the dominance of French and Belgian soil scientists, who had been most active up until then in most parts of Central Africa. The level of information varied, but it was estimated that around half of the area was covered by high quality maps, while the remainder was covered by less precise maps or extrapolations (d'Hoore, 1964).

It is not easy to obtain information on the progress of soil mapping within Africa or information as to how much has been incorporated into one or other type of database, but information that could be obtained is presented in Table 32.1.

The existing soil information was incorporated into the first global soil map (FAO-UNESCO, 1981). However, due to its global coverage, as well as the need to correlate the many existing soil classification systems, the resolution of the map was low (1:5 million scale) and lacked much of the qualitative information on soil properties that would allow a soil map to be further interpreted.

Soil Databases in Africa 32-5

32.4 Soil Databases

The aim in creating a soil database is to move from the previous system of paper maps and reports to one where a geographic information system (GIS) can be used to produce a polygon-based digital map with geo-referenced point data, with the digital report and soil profile database hyperlinked, so that all the information is available from a CD-ROM or on the web (van Ranst and Verdoodt, 2010).

32.4.1 Reconnaissance Scale

In the early 1990s, there was a movement, started at ISRIC in the Netherlands, for a global inventory of soil and terrain resources, at an approximate scale of 1:1 million, so that the SOTER (SOil and TERrain database) approach came into being. Applications arising from the SOTER databases have been developed to evaluate a range of district and regional development issues. Early examples of these applications were an erosion hazard map under current land use for the Kajiado District of Kenya, and the physical suitability map for rain-fed sorghum in western Kenya (Van Engelen and Mantel, 1995). In each case, the FAO Framework for Land Evaluation (FAO, 1976) was used together with digital SOTER data to focus on development issues by adopting mixed quantitative and qualitative land evaluation approaches (van Lanen et al., 1991). The applications for Kenya (1995, updated in 2007) were followed by similar projects in northeastern Africa (1998), southern Africa (2003), central Africa (2007), and a host of other country databases (Senegal/Gambia, South Africa, Tunisia) in 2008.

Two projects concerning the improvement of digital soils coverage in Africa have recently commenced. They are the "Soil Atlas of Africa" project and the "African Soil Information Service" (AfSIS).

The "Soil Atlas of Africa" project (www.eusoils.jrc.ec.europa. eu/library/maps/africa_atlas/index.html) is a joint initiative between the Joint Research Centre (JRC) of the European Union, ISRIC, the FAO, and the African Soil Science Society, where the

aim is to collect as much as possible of the significant soil information for Africa that does exist and to digitize it to create a soil atlas, similar to the "Soil Atlas of Europe" (European Soil Bureau Network of the European Commission, 2005). The atlas is planned to be published during 2011.

The AfSIS project (www.africasoils.net) is based on the concept of supplying information on "soil health," which can then be related to soil productivity. The project, which is due to run from 2008 to 2012, has obtained funding from the Bill and Melinda Gates Foundation and the "Alliance for a Green Revolution in Africa" (AGRA). One of the project aims is to establish a total of 60 soil fertility field trials in five countries containing significant agro-ecological zones called "sentinel landscapes" and then to link the field data to remotely sensed information so that the findings are applicable to the widest possible area.

Remote sensing techniques are possibly one of the most valuable techniques for improving the quality of soil-based databases in Africa, due to the size of the areas involved. By using such tools as the 250×250 m resolution MODIS imagery, zones can be identified, which can be further investigated by focused ground-truthing programs. One area where this has been applied is in Egypt, where changing salinity levels in the vicinity of the Nile delta have been studied (Hamdi and Abdelhafez, 1998).

The AGRA project (www.agra-alliance.org), whose board is chaired by former UN Secretary General Kofi Annan, has as a goal to support smallholder farmers in food production, while protecting the environment and adapting to climate change. One of the programs to achieve this is concerned with enhancing soil health by improving the levels of soil testing and mapping, and it is surely here where the implementation of digital soil data, especially at more detailed scales in specific focus areas, might make a significant contribution to food security on the continent.

32.4.2 Detail Scale

Instances where more detailed soil information (1:5,000–1:50,000 scale) has been collected and digitized are scarcer, but those that could be sourced are listed in Table 32.2. The priority

TABLE 32.2	Selected Soil Databases at Large (Detailed) Scale	

Region	Country	Scale	Map Type	Area (km²)	Profile Classification	Soil Analyses	Information Content	Reference
West Africa	Cameroon	1:50,000	Mbonge-Boa (Soil suitability)				Soil associations and land suitability	Anderson (1982)
North Africa	Egypt	1:50,000	Soil physiographic maps, upper and lower Egypt				Soil map and land use map; reclaimed areas	Hamdi and Abdelhafez (1998)
	Ethiopia	1:50,000	Jelo catchment, Chercher highlands	3,250	FAO (1988)	50 profiles	Land suitability information	Ahmed (2003)
Southern Africa	Botswana	1:20,000	Semi-detailed soil survey				Soil suitability for irrigation	Mitchell (1968)
	South Africa	1:50,000	PWV Peri-urban survey, Gauteng province	14,800	MacVicar et al. (1977)	40 soil profiles	Soil types with depth and texture class for land use planning	Yager et al. (1990)

in many countries was to have any existing reconnaissance scale data converted into digital format, so that large-scale digital soil information is not common.

32.4.3 Ultra-Detailed Scale

In areas of the continent where high-value, intensive agriculture is practiced (such as several areas in South Africa), soil information (descriptive and analytical), which is spatially defined using a GPS, is collected at a very detailed scale. These data, which may be at an interval as small as 2×2 m, may then be used in precision farming applications for accurate and cost-effective application of fertilizers and other ameliorants. However, most of these datasets are commercially based and are privately operated so that they are not currently available for public use.

Precision agriculture embraces many different permutations and varieties of philosophies. The theoretical considerations should be balanced with practically implementable operations within the established farming system. The production potential of rain-fed arable cropping can often only be achieved when the physical and chemical limitations have been reduced or eliminated. This implies access to comprehensive and reliable soil and climate information, enhanced by digital information technologies, and supported by sound scientific research.

Precision agriculture technologies are gaining prominence in the central and western grain-producing regions of South Africa with a sub-humid climate. Water extraction by plant roots and specific nutrient deficiencies are the primary soil limitations to crop growth (Muller, 2008). Soils comprise fine to medium aeolian sandy profiles, often underlain by slowly permeable plinthic or gleyed horizons. The latter are responsible for improved delivery of plant available water, particularly in low rainfall seasons, and hence, significantly reduce crop yield risk. The digital capture of detailed farm scale soil survey information identifies the land areas most suitable for sustained grain crop production. Soil fertility sampling at increasing levels of detail is used to overcome soil fertility and acidity imbalances, while GPS technology at harvest provides a visual record of grain yields across agricultural fields. These database technologies coupled with research and agricultural advice systems are contributing towards economically sustainable production systems.

32.5 Soil Profile Databases

In addition to soil mapping information at its various scales, another type of information contained in soils databases is that of profiles, which is usually linked to the surrounding soil pedon. Nachtergaele and van Ranst (2003) state that of the 4353 soil profiles contained within the Global Pedon Database created by ISRIC, a total of 1799, or 41%, lie in Africa. In addition, several countries have their own database of soil profile information, such as South Africa, where approximately 2500 georeferenced soil profiles, each with a full profile description and analytical data for each horizon, have been collated as part of their national land type survey program.

32.6 Database Interpretation and Utilization

A soil database is only as good as its ability to be accessed and utilized, so that the basic soil data contained therein can be interpreted for a variety of uses. Two examples of national soil databases (at varying scales) where such use has been made are those of Rwanda and South Africa. Rwanda is a small country, with an area of just under 25,000 km², so that it was possible to carry out soil mapping between 1981 and 1994 of the whole country at 1:50,000 scale (Imerzekene and van Ranst, 2001), with over 1800 profiles described and analyzed and all of the map polygons digitized using ArcView. The final maps are used not only for traditional agricultural purposes, but also for such purposes as settlement planning, disaster-preparedness planning and high-input agriculture. The system allows easy updating, modification or reorientation depending on the requirements of the different Ministerial departments who are going to use it. As such, the land resources information can be used more efficiently and accurately allowing the Government of Rwanda to investigate specific agricultural and environmental issues in a timely manner.

In contrast, South Africa is a much larger country, with an area of approximately 1.2 million km², so that the soil mapping program, which was carried out between 1972 and 2002, was done at a scale of 1:250,000 (Land Type Survey Staff, 1972-2002). The project, known as the Land Type Survey, has over 7000 unique mapping units, or land types, each one of which is a combination of soil pattern, terrain type and macroclimate, and around 2500 fully described and analyzed soil profiles. One of the benefits of the database is that algorithms can be written to assess each map unit for specific crop suitability, and the algorithm inputs can be altered very readily for ease of comparison of results. The information is widely used for municipal and regional planning, identification of potentially problematic areas (such as erodible soils), and even multi-resource research projects, such as possible links with the occurrence of soilborne pathogens or weeds. More and more applications are being discovered as a wider range of potential users (e.g., engineers, planners, and agronomists) become aware of the content of the database.

In addition, South Africa has a more detailed (1:50,000 scale) soil database for the densely populated area around Johannesburg and Pretoria in Gauteng Province (Yager et al., 1990). Here, the soil information is used to identify valuable areas of productive agricultural land in order to protect them from peri-urban expansion against the background of ever-increasing urbanization and consequent competition for land resources.

32.7 Conclusion

Despite the inconsistent history of soil database compilation in Africa, coupled with communication and other limitations of the past, it seems that the supply of digital information is improving and that there are a number of initiatives underway to collect, check, and distribute the information to land users who require it. For the benefit of the population of Africa as well as the need to ensure their future food security using a fragile soil resource, it is to be hoped that this situation continues.

33.1 Introduction

Many of the concepts that students learn in soil, crop, and environmental science courses are inherently spatial. Soils vary across landscapes in predictable, repeating patterns. Certain soils and landscapes are better for particular crops than others. An environmental problem may impact a whole watershed, not just the point at which a contaminant is introduced. Patterns of land uses, whether for crop production, forestry, wildlife habitat, or urban development, vary spatially in response to soils, topography, geology, human infrastructure, and many other factors. Although we implicitly acknowledge the existence of spatial patterns in our soil, crop, and environmental science courses, our ability to explicitly observe these spatial patterns visually and make them clear to our students has, in the past, been limited. Geographic Information Systems (GISs) and the recent availability of detailed digital soil survey data, particularly in the United States, along with increasingly detailed Digital Elevation Models (DEMs) worldwide, allow us to visualize and analyze such complex geospatial information in new ways, and to use them to enhance teaching and learning. Research has repeatedly shown that a dynamic, active, visually rich learning environment significantly increases comprehension and retention relative to a more passive, auditory environment (Bransford et al., 2000).

Aside from the pedagogic reasons outlined earlier, two recently published reports, *Learning to Think Spatially: GIS as a Support System in the K-12 Curriculum*, and *Beyond Mapping: Meeting National Needs Through Enhanced Geographic Information Science* (National Research Council, 2006a, 2006b), make compelling arguments for the need to incorporate spatial thinking and spatial technologies throughout our curricula. Teaching

and learning soil science using a geospatial approach is one way to accomplish this.

Advances in computer hardware now allow us to take powerful, reliable computers to the field that can run state-of-the-art GIS software and have the capacity to store large GIS datasets. This makes it possible to have at one's fingertips a wide variety of different maps that can be zoomed in to show detail or zoomed out to show the overview at any time. The addition of a Global Positioning System (GPS) receiver allows for the display of one's exact location on the map at all times. The result is an engaging and informative set of maps through which one can see and understand the soil landscape in a new geospatial context. We have only begun to take advantage of the powerful, learner-centered instructional tools that GIS and soil geodatabases have to offer. The purpose of this chapter is twofold: (1) to describe how we use, and continue to evolve our use of, these new tools and databases in our undergraduate and graduate soil, crop, and environmental science courses; and (2) to provide practical suggestions for those wishing to implement a similar approach in their own teaching program.

This chapter is divided into three parts. First, we begin with a description of how we have incorporated USDA's Web Soil Survey into several of our soils courses in addition to or in lieu of paper maps. This is the easiest approach to incorporate soil geodatabases into a teaching program, although Web Soil Survey covers only the United States and its territories. Second, we describe how we have incorporated a "teaching with GIS" approach into our field-based pedology course by taking GIS to the field on rugged tablet PCs equipped with GIS software and GPS receivers. This approach requires considerable initial work on the part of the instructor, but with the result that the maps can be customized and optimized to teach particular concepts.

Third, we conclude with a brief description of how geospatial soils information can be delivered using Web 2.0 technology such as Google Earth.

33.2 Teaching and Learning with Web Soil Survey

We began using Web Soil Survey in our introductory Soil Science course as soon as Web Soil Survey became available in August 2005. Students are taught in lecture how to use both printed copies of County Soil Surveys and the Web Soil Survey to access valuable soils information. Following an introduction in lecture, students come to our Soils Resource Center where they spend approximately 2h using both County Soil Surveys and Web Soil Survey to answer questions about their home communities or about Tippecanoe County where Purdue University is located. Students develop skills in finding information about soil types, land use, soil classification, engineering properties, and crop, forest, and wildlife recommendations for each soil in a county. Since Soil Science is a prerequisite for all other crops and soils courses in the department, all instructors in the department are able to now use the Web Soil Survey database as a primary tool in any class project utilizing soil and landscape information. Students who are not from Indiana can access information about their home county, or instructors can assign projects related to land use anywhere in the United States This provides students with a direct understanding of how soils and their use vary not only in Indiana but across the country. Examples of projects assigned to students include golf course construction and fertility planning, nutrient management plans for farms and livestock operations, and urban and suburban building projects. Soil and suitability maps and data tables can be directly printed from the web and included in student project reports without retyping them. Since Web Soil Survey became available, students have been more likely to utilize soil survey data because they are accessible from anywhere at any time, making it easy to include soils information as part of their project reports in multiple courses. Students rate the use of the Web Soil Survey for these projects as an extremely valuable part of their soils educational experience and many of them indicate in their senior exit interviews that they use the Web Soil Survey in courses outside of the Agronomy Department as a tool for class projects.

Web Soil Survey and the printed County Soil Surveys that preceded it are designed to deliver detailed soil survey information for relatively small "areas of interest," generally an individual field, farm, or other area of less than a few thousand hectares, where the goal is to obtain information for a particular use or management of the area. Both Web Soil Survey and County Soil Surveys are excellent for this purpose, but they are not designed to illustrate spatial aspects of soils and geomorphology that may occur over tens or hundreds of kilometers. The vast amount of publicly available soil and other geospatial data now available digitally provides an opportunity for new approaches to teaching and learning about soils and the landscapes in which they occur.

33.3 Teaching and Learning Using GIS and Soil Geodatabases in the Field

In the summer of 2005, we began experimenting with how we could utilize the newly available soil and geomorphology data in our teaching program, and in the fall of that year, we initiated a "teaching with GIS" approach in our Soil Classification, Genesis, and Survey course using three tablet PCs and a minimal GIS dataset. We now routinely take our class on weekly 3 h field labs and on two, all-day field trips along with 14 tablet PCs and a GIS dataset that has grown to encompass the entire state of Indiana (92,895 km²) (Figure 33.1). Our focus is to teach students how soils and landscapes vary spatially over many different scales, and how the soil geomorphic concepts illustrated with diagrams in the classroom correspond to actual features observed in the field. Students can zoom out for an overview and zoom in to see details on the maps displayed on the computer they have in their hands. They can quickly access maps of topography, soil parent material, soil drainage class, presettlement vegetation, and other maps, thereby learning how the soil that they just examined in a pit is distributed over larger areas than they can see from their current location. They can query the map to obtain more information on individual soil delineations, and, soon, to view a diagram of the dominant soil within the map unit. This approach has significantly altered how we teach field soil science and what we teach (we have learned many new things ourselves), and has significantly impacted student learning.

We continue to incorporate the tablet PCs and "teaching with GIS" into an increasing number of our soil, crop, and environmental science courses. For those wishing to incorporate a similar approach into their own teaching program, the following sections provide information on computer hardware considerations, development of the GIS dataset, and how we teach with GIS.

FIGURE 33.1 A student using a tablet PC and GIS software on a bus during an all-day soils field trip. The small, gray device mounted on the upper right corner of the tablet PC is the GPS receiver. The pen in the student's right hand is used to manipulate the map.

33.3.1 Hardware Considerations

Almost any laptop computer can be used in the field, but whether or not it will be a useful tool for teaching and learning depends on a number of factors.

Reliability is obviously an important issue. If the computers will only be used in a vehicle and can always be kept clean and dry, then normal laptops will probably work. If, on the other hand, the computers are to be used while walking in fields, where dust, sand, or seeds are encountered, or if the computers will be handled a lot, as when people get into and out of a vehicle frequently, then more robust "rugged" laptops or tablet PCs are more appropriate.

We use the PCs almost exclusively for displaying maps. For this, the major user interaction with the PC consists of manipulating check boxes to turn data layers on and off, zooming and panning the map, and choosing items from dropdown boxes. Since there is almost no need to enter text, tablet PCs are considerably more practical than laptop computers with a keyboard. A tablet PC consists of one rectangular unit the size of a large book (Figure 33.1). There is no physical keyboard (or the keyboard is folded under and not used) and the user interacts with the tablet PC exclusively through the use of a pen. A laptop computer with its flip up screen is less practical, particularly in the confined space of a van or bus.

The display screen is an important consideration. If the screen cannot be seen under the conditions under which the computers are to be used, very little learning can occur. If the computers are to be used frequently in bright sunlight, then a bright sunlight-readable screen is essential. If the computers are used mainly inside of a van or bus, a screen that does not perform well in bright sunlight may still work well in the lower light conditions inside the vehicle. If one computer is to be shared by two or more students, it is important that all viewers can see the image on the screen. The image on some screens is difficult to see when viewed at approximately 45° from the normal, while on other screens it is not. Testing a computer under the conditions under which it will be used prior to purchase can prevent disappointment and frustration later.

Knowing where one is on the map at all times is essential to the educational experience of using GIS in the field. There are many options in choosing a GPS receiver. All that is needed, however, is an inexpensive, consumer-grade GPS sensor that can be connected to the computer running the GIS software. There is no need for the maps or additional software that is often sold with the receiver. Also, positional accuracy of a few meters is sufficient. It is important, however, to use a "high sensitivity" GPS receiver as it will typically maintain a GPS "fix" in wooded areas and when the receiver is inside of a vehicle. Older "standard sensitivity" receivers will not. The receiver can be connected to the computer via a wired Universal Serial Bus (USB) or serial port connection, or via Bluetooth® wireless technology. The wired receiver may be easier to set up initially, but has the disadvantage of requiring a connector plugged into the side of the computer, which may be susceptible to damage as the computer is handled frequently in the field. A wireless connection eliminates the cord, but requires Bluetooth® connectivity on the host computer and may be a bit more difficult to setup in some situations. The battery in the wireless GPS receiver will need to be charged separately from the host computer, whereas a wired GPS receiver may or may not have a separate battery.

Learning stops when the computer battery dies, so power management to assure that the computers remain functional for the duration of the time in the field is essential. High-capacity batteries, if available, should be considered. Some computers offer hot-swappable batteries. If the computers will be used in a vehicle, 12V power adapters are more convenient and less expensive than additional batteries. Setting the power management so that the screen goes blank and the hard disk is shut off after a few minutes of inactivity will greatly extend battery life.

There is no substitute for experience when taking GIS to the field. When just beginning, use of an existing laptop and an inexpensive GPS receiver is a good way to obtain experience without much additional expense. When considering purchase of new equipment, it makes sense to obtain a demo unit and use it under field conditions prior to placing an order. The complexity of getting the computers, GIS software, and GPS units working together correctly may require specialized assistance from computer professionals. It is important, however, that the instructor or a teaching assistant be familiar enough with the hardware and software so that minor problems that pop up can be addressed in the field. An inoperative computer or a computer that is not operated effectively by the instructor is not useful for learning. In addition to planning for specific teaching goals, one must plan ahead to be sure that the computer hardware will be ready to go when students arrive for class, and that the hardware will function for the duration of the class time. We typically have the computers ready to go when the class begins so that we do not waste valuable class time setting up computer hardware.

Computer hardware and software continues to evolve rapidly. When appropriate software becomes available, new devices such as Apple's iPad (http://www.apple.com/), for example, may make it even easier to teach and learn with GIS in the field.

33.3.2 GIS Software

We use ArcGIS 9 software (ESRI, Redlands, California) running under the Windows XP operating system. ArcGIS 9 includes support for GPS input. Other GIS software might be suitable as well, so long as it supports GPS input and the large datasets which one is likely to develop, but we have worked only with the various versions of ArcGIS 9 to date.

33.3.3 Development of the GIS Dataset

Over time, we have developed an approach for structuring our GIS dataset so that it functions as an effective teaching tool in our courses. Two distinctly different datasets are essential to making a GIS-based approach effective in teaching. One is the soil survey data that cover the area of interest, the other is a DEM

of the same area. Each dataset alone is informative by itself, but in combination, the information conveyed is vastly greater than the sum of the individual parts. Additional data layers are important as well, but the soils–DEM combination is central to learning about soils using GIS in the field.

33.3.3.1 The Digital Elevation Model

A DEM consists of a raster dataset in which the value for each cell represents elevation. DEM data are available for all parts of the world. Elevation data at 90 m resolution is available from the Shuttle Radar Topography Mission (USGS, 2008) and a 30 m worldwide DEM has just become available from the Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) program (NASA, 2009). Data at 30 and 10 m resolution are available for the entire United States (USGS, 2009) and data at even higher resolution may be available for certain areas. Elevation data for the state of Indiana, for example, are available at 1.5 m resolution (ISDP, 2009). New data are constantly becoming available, and in many cases this data can be downloaded from the Internet.

In general, one should use the highest quality, highest resolution data available for the area of interest. The available data should be evaluated carefully, however, because the highest spatial resolution data may not necessary provide the highest elevational quality. If very high resolution data are available, it is advantageous to determine whether or not it can be resampled to a lower resolution without loss of significant information. We have found, for example, that the 1.5 m DEM dataset for Indiana can be resampled to 5 m resolution without compromising our ability to see subtle geomorphic features, but with a substantial reduction in the size of the dataset.

A DEM hillshade should be calculated from the original DEM data. A hillshade is a black and white image that shows the hypothetical shadows and highlights that would occur on the Earth's surface for a given sun position (usually 45° above the horizon and 45° west of the viewing direction). The hillshade, therefore, shows slope but no longer contains information on elevation. The hillshade is one of the most useful layers in the dataset because it graphically illustrates the topography. The hillshade is used as a base layer for other data, particularly soils data.

The hillshade should be viewable by itself because some topographic features are more easily seen on the opaque black and white hillshade. To best illustrate elevation, however, a semitransparent (50% transparency) sequential color scheme should be applied to the DEM data and then overlain on the opaque hillshade. These two layers are illustrated in Figure 33.2.

33.3.3.2 Soil Data

Soil survey data at this time are typically available in a polygon format, and most, if not all, of the soil survey data currently available have been digitized from existing paper maps. The data consist of two parts: (1) spatial data, which consists of the polygons that delineate the map units within the survey area, and (2) tabular data, which consists of a table (the attribute table) that tabulates the various attributes associated with each map unit. A map unit

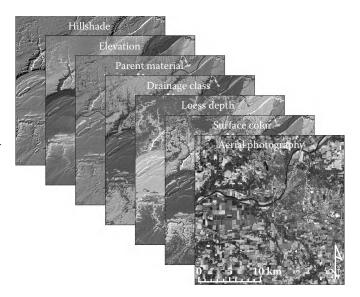

FIGURE 33.2 (See color insert.) Examples of some of the different kinds of maps available in our GIS dataset illustrated by a portion of Tippecanoe County, Indiana. Note the obvious correlation between features shown on the different maps.

may consist of thousands of individual polygons, but each polygon of the same map unit is associated with only one unique set of values in the attribute table. The attribute table typically contains information on many different properties of the map unit, such as map unit name, soil classification, soil drainage class, moisture holding capacity, etc. Thus, by selecting different columns in the attribute table, one can easily prepare maps for any property represented in the attribute table. If a soil property of interest is not represented in the attribute table, one can add additional columns to the attribute table with one's own interpretation, although this can be quite time consuming if the dataset is large, and it requires an intimate knowledge of the soils of the area.

Soil survey data are available from a variety of sources and an Internet search may be all that is needed to locate useful data. Detailed soil survey data for the entire United States can be downloaded from the U.S. Department of Agriculture, Natural Resources Conservation Service's Soil Data Mart (Soil Survey Staff, 2009). Two types of data are available: (1) the U.S. General Soil Map (STATSGO2), and (2) the Soil Survey Geographic (SSURGO) Database. The SSURGO database consists of the detailed order 2 soil survey data covering almost the entire United States. We have found the SSURGO data to be the most useful for our purposes.

Most of Indiana was glaciated during the Pleistocene, and the northern two-thirds was glaciated during the Wisconsin Glaciation, which reached its maximum extent in Indiana only ~21,000 years ago. Thus, there is a very close correspondence between the various glacial deposits and the properties of the soils that formed in and on them. As a result, we rely heavily on a soil geomorphological approach in teaching soil science in Indiana. The single most useful map in our GIS dataset is a dominant soil parent material map that we developed from our own interpretation of the SSURGO data. Since many soils in

Indiana developed in two and sometimes even three different parent materials, we define the dominant soil parent material as that material with the greatest influence on other soil properties, or a material that highlights a particular distinguishing feature. Usually, the dominant soil parent material is the lowest one in the profile, but it may be at the surface, for example, surface layers composed of organic soil material. By carefully grouping soil map units with similar soil parent materials, we are able to visualize the soil landscape in new ways. By making the dominant soil parent material layer transparent and overlaying it on the DEM, outwash plains, flood plains, dune fields, and other geomorphic features stand out in stark contrast to the surrounding till plains (Figure 33.2).

A separate loess depth map (Figure 33.2) provides information about the loess (wind-blown silt) that covers large areas of the state. Maps of soil drainage class and surface color (which generally correlates with presettlement vegetation) (Figure 33.2) provide information on other soil properties or soil forming factors that we discuss in class.

33.3.3.3 Other Maps and Data Layers

A number of other maps and data layers round out our GIS dataset. Color aerial photography (Figure 33.2) is particularly useful when one is walking over the landscape and the focus is on one's immediate surroundings. Topographic maps, referred to as Digital Raster Graphics (DRGs), are scanned versions of traditional paper topographic maps. DRGs can often provide information on the names of physical features not found in other databases. Since many were last updated 20, 30, or more years ago, traditional topographic maps provide a useful historical perspective. Topographic lines can be used to show topography, although their use is largely supplanted by the DEM. Hydrography, the centerlines or boundaries of rivers, streams, and lakes, shows where water bodies are located. Roads and towns are important for orienting oneself relative to observable anthropogenic features. Historic maps (we have, e.g., a 1852 map of the state of Indiana) provide a historical perspective and show, in some cases, how humans have influenced the landscape. Maps of bedrock geology and topography of the bedrock surface provide insights on what is below the upper 2m of the Earth's surface that soil scientists usually focus on. In short, any map or data layer can and should be included in the GIS dataset, so long as it serves to further one's teaching and learning objectives.

33.3.3.4 Hierarchy of Data Layers

Table 33.1 lists the hierarchy of data layers that we use most frequently. Layers at the top of the list, if they are turned on, overlie layers below them. The user typically turns on only a few layers at any one time, essentially customizing the map as needed. We have found that soil layers are most informative when they are semitransparent and paired with an underlying opaque hillshade. The two are turned off and on as a unit. Although it is tempting to overlay several semitransparent layers, this quickly becomes visually confusing. It is far more informative to turn an overlying layer off and on to compare it with an underlying layer.

-	al Hierarchy of D	
Layer Name	Туре	Comments
Cities and towns Reference	Points	Important for locating oneself on a map and for describing locations to others Political boundaries
State outline	Lines	
County outlines	Lines	
County names	Labels only	Turn on as needed

Elevation	Raster, 50% transparent	DEM data rendered as a sequential color scheme
Hillshade	Raster, opaque	
Hillshade	Raster, opaque	The DEM hillshade alone is often useful for seeing subtle geomorphic features

^a These layers function as a unit and are turned off and on together rather than individually.

33.3.3.5 Other Considerations

Most maps and data layers "work" best within a particular range of scales or "zoom" levels. In general, there should be enough information on the screen to make the map interesting and informative, yet not so much as to be confusing. The speed at which one is moving is an additional consideration. Ideally, most people wish to see noticeable movement of the GPS position marker across the map as they move over the landscape so that they can see how the physical features of the landscape correspond with the information depicted on the map. Thus, when driving across the landscape at 80-100 km h⁻¹, a more general map, like the dominant soil parent material map that we described earlier, viewed at a scale of around 1:50,000 is more informative and appropriate (Figure 33.3a). On the other hand, when walking over a field at a speed of 4-5 km h⁻¹, an aerial photograph overlain by detailed soil delineations at a scale of 1:10,000 may be the most informative map (Figure 33.3b). With experience, one quickly discovers which map and scale are most appropriate for a particular situation. The instructor, however, is in control of what can be displayed by the GIS and careful design

of the various map layers is critical to making GIS an effective teaching tool in the field. Considerable thought, as well as trial-and-error, is generally necessary to create effective maps for a particular landscape. Students should be able to turn most map layers on and off as needed. The location of roads and towns may not be necessary to understand soil and landscape features, but they are essential to making the viewer feel correctly oriented on the map even though the GPS shows the position at all times. The types of soil features highlighted by the GIS will likely be different in different landscapes. Every landscape has a story to tell. It is the role of the instructor to determine what that story is and how best to tell it.

The number of classes displayed on any one layer should be as small as possible or it becomes very difficult to select distinctly different colors to symbolize the map. Five to seven classes is generally considered optimal (Brewer, 2002), but more classes may be necessary to prevent the map from becoming too general. We have used up to 16 classes, but at the risk of occasional ambiguity in a map. One should keep in mind that the screens on different computers may not display colors with the same intensity or fidelity, so colors that look distinctly different on one computer may appear almost the same on another. ColorBrewer (Brewer, 2002) is useful in providing guidance on selecting colors to symbolize a map. Poorly selected colors can make an otherwise informative data layer incomprehensible. Colors should be selected with an eye toward assuring that the map is clear and meaningful at a glance. If possible, colors should evoke the particular soil property being displayed. Our color scheme for soil drainage class, for example, assigns a deep brown color to the "well drained" class to evoke the homogeneous brown colors typical of our well drained soils, while increasingly grayer colors are assigned to wetter drainage classes to evoke the gray colors of soils with wetness characteristics. About 8% of men and 0.4% of

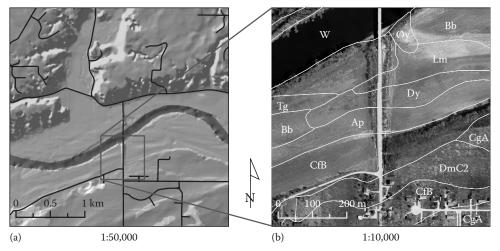

FIGURE 33.3 (See color insert.) The most informative map often depends on how fast one is moving over the landscape. (a) A more general thematic map, like this dominant soil parent material map displayed at 1:50,000, is informative and usually most appropriate when one is traveling in a vehicle. (Tan, glacial till; green, glacial outwash; light blue, recent alluvium; yellow, eolian sand and/or other sandy sediments.) (b) An aerial photograph overlain with the detailed soil delineations and displayed at 1:10,000 is often the most informative map when one is walking across the landscape. The polygons are queried individually to obtain information about the soils they represent.

women are affected by red-green colorblindness (Brewer, 2002). Ideally, the color scheme should be designed with this in mind so that all students will be able to interpret the maps correctly.

To provide the best user experience, the map should refresh as quickly as possible when it is zoomed and panned and when layers are turned on and off. Raster data are usually displayed very quickly, but polygon data can take a considerable time to display, particularly when more than a few thousand polygons are within the field of view. To increase the speed at which the map refreshes, polygon data should be rasterized. Raster data display more quickly at various resolutions when successive lower resolution copies of the data are stored along with the original data, a process called pyramiding. GIS software typically contains different algorithms for pyramiding raster data. It is worthwhile to try different algorithms for a particular dataset because some produce more pleasing small scale maps than others.

33.3.4 Pedagogic Aspects

Even though we now regularly use GIS while we are in the field, like most pedology classes, we still have our students study soil profiles and write morphological descriptions of them. We have not appreciably reduced the number of soil profiles examined or the number of auger holes bored. What we have done, however, is to make the time that we spend driving to field sites more productive by using the tablet PCs. To structure the learning process, we provide worksheets that ask our students to view particular layers at given scales at specific locations along our route so that we can be sure that they can locate and identify the features that we wish them to see. When we reach our field destination, we discuss the worksheets and go over what we expected the class to see along the route. Thus, over the course of the semester we are able to guide our students to formulate their own generalizations of how soils occur spatially and how the few soils that they saw in pits or auger borings are distributed more widely over the landscape. We also encourage our students to explore the maps on their own by zooming in and out and examining different layers as they see fit, thereby becoming active participants in their own learning.

The response of our students has been very enthusiastic and all have reported significant increases in comprehension and understanding of the course material, which our assessment has shown as well. The power of GIS to teach soil science became clear to us as instructors because we have learned many new and interesting things ourselves. For example, although we already understood the general glacial geomorphology of the area near campus, the full extent of the rich variety of subtle glacial features was not evident until we developed the GIS dataset. The soils vary from one geomorphic feature to the next, sometimes only slightly, sometimes greatly. We are now able to explain differences in soil properties in a geomorphic context rather than just describing and interpreting each pedon individually. The result is a rich new dimension in how we describe, and how our students understand, the soil landscape around them.

33.4 Teaching and Learning Using a Web-Based Geobrowser

Although taking GIS to the field on dedicated rugged tablet PCs has significantly enhanced teaching and learning, it has the disadvantage of reaching only a relatively small number of students in a few classes. To integrate a geospatial component into more of our undergraduate and graduate soil, crop, and environmental science courses, we have just launched the Integrating Spatial Educational Experiences (Isee) web site (http://isee.purdue.edu/), which will allow our students to access geospatial soils information via the Internet at any time or place. In addition to use in our own courses, we anticipate that the Isee web site will be used by students, teachers, and the general public throughout the state.
